## DECLARATION

I hereby *declare* that the Research Synopsis entitled “**Synthesis and Characterization of Silver nanowires and MoS<sub>2</sub>/Metal oxide hybrids for electronics and energy applications**” which is being submitted to the **National Institute of Technology Karnataka, Surathkal** in partial fulfillment of the requirements for the award of the **Degree of Doctor of Philosophy** in the **Department of Metallurgical and Materials Engineering**, is a *bonafide report of the research work carried out by me*. The material contained in this Research Thesis has not been submitted to any other University or Institution for the award of any degree.

Place: NITK, Surathkal

Date: 29.11.2021

## **ACKNOWLEDGEMENT**

This thesis becomes a reality with the kind support and help of many individuals. I would like to extend my sincere thanks to all of them.

I express my heartfelt gratitude to my research supervisor Prof. Udaya Bhat K., Department of Metallurgical and Materials Engineering, for his continuous support, and motivation and immense knowledge that he has shared with me, whilst allowing me the room to work in my way. His unwavering guidance has helped me in making the appropriate decisions and to remain optimistic during critical times.

I am indebted to The Director, NITK and present Head of the Department, Prof. K. Narayan Prabhu and former department heads Prof. Jagannath Nayak and Prof. S. Anandhan. They have extended their generous support by providing required facilities and support during my doctoral research work. I would like to acknowledge MHRD, Govt. of India for providing financial support for this work in the form of the Institute research fellowship.

I am very thankful to my research progress committee members, Dr. Saumen Mandal, Assistant Professor, Department of Metallurgical and Materials Engineering and Dr. Srikanth Bontha, Associate Professor, Department of Mechanical Engineering, for their valuable technical input and encouragement during this research work.

I extend my sincere thanks to Prof. M.N. Satyanarayan, Department of Physics, Dr. Shashi Bhushan Arya, Assistant Professor and Dr. Saumen Mandal, Assistant Professor, Department of Metallurgical and Materials Engineering for providing me their laboratory facilities to carry out my research work. I express my heartfelt gratitude to all the faculties of Dept. of Metallurgical and Materials Engg. for their constant guidance and support

It has been my pleasure to have supportive fellow researchers who would always help with my research work. I thank Dr. Arun Augustin, Dr. Prashant Huilgol, Dr. Jayalakshmi M., Dr. Sunil Meti, Dr. Nandana M.S., Mr. Sudhish R. and Mr. Naveen Bharadishettar. I express my gratitude to all the fellow research scholars of the department. I am deeply grateful for my friends Dr. Sivananth M., Dr. Marimuthu C.,

Dr. Pragadeesh K.S, Dr. Ajmal T.S., Dr. Raghavan S., Dr. Kamal Babu, Dr. Baskaran T., Mr. Praveen J., Dr. Rajeshkumar R. and Dr. Mohamed Jaffer Sadiq M.

I am thankful to all the non-teaching staff members of the Department of Metallurgical and Materials Engineering, Mrs. Sharmila, Mrs. Rashmi, Mr. Yeshwant, Mr. Dinesh, Mrs. Vinaya, Mr. Sundar, Mr. Sachin and Mr. Lokesh for their kind cooperation and help. I also thank Central Research Facility (CRF), NITK for providing the characterization facilities for my research work.

There are no words to express how fortunate I am to have such an understanding, affectionate and supportive family. I thank my parents, sister, brother-in-law and their kids, without whom I could not have completed this journey. I thank my relatives, friends and well-wishers who always encouraged me during this research work.

PRABUKUMAR C.

## ABSTRACT

The present study focuses on two important aspects of next-generation electronics and energy storage devices. One is the flexible transparent conductive electrode fabricated using silver nanowires. Another is the ZnO anode used in zinc alkaline batteries. The silver nanowires transparent conductive films are the potential alternative to widely used high-cost, brittle indium tin oxide (ITO). The silver nanowires are synthesised by following the polyol method. Among many synthesis parameters, the oxygen scavenger is important for the growth of longer silver nanowires. These oxygen scavengers (ex: Cu or Fe ions) help to prevent the blocking/etching of silver seed particles from atomic oxygen adsorbed on their surface. This work explores the use of manganese ions as the oxygen scavengers during the silver nanowires synthesis due to the multiple oxidative states of manganese. The silver nanowires are synthesised in different chloride conditions: no chloride, NaCl, CuCl<sub>2</sub> and MnCl<sub>2</sub>. The silver nanowires synthesised with the presence of Mn(II) ions and Cl<sup>-</sup> ions show more uniform, longer nanowires with a smaller diameter than that synthesised with the presence of Cu(II) ions. The transparent conductive films are fabricated by the spray coating method using the silver nanowires synthesised with Mn(II) ions. Three films with optical transparency (at 550 nm) and sheet resistance of 81% & 40 Ω/sq., 79% & 29 Ω/sq. and 80% & 34 Ω/sq. are produced. The silver nanowires film shows excellent mechanical flexibility. The heater test conducted on the silver nanowires film achieved a temperature of 90 °C.

Factors like the dissolution of Zn anode, hydrogen gas evolution, shape change make the Zn/ZnO anode in zinc alkaline batteries difficult to recharge. These problems can be mitigated by tailoring the morphology of the anode and incorporating desirable additives with the anode. Tin oxide (SnO<sub>2</sub>) is an excellent additive to Zn/ZnO. The poor charge transfer within SnO<sub>2</sub> due to volume expansion and microcracks are the drawbacks of using SnO<sub>2</sub>. The liquid phase exfoliated MoS<sub>2</sub> nanosheets are used as the support material to facilitate the charge transfer between the SnO<sub>2</sub> nanoparticles. The nanocomposite of MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles (MoS<sub>2</sub>-SnO<sub>2</sub>) is prepared by the ligand exchange process. The ratio of MoS<sub>2</sub> in SnO<sub>2</sub> is optimized by conducting the supercapacitor characterizations such as cyclic voltammetry, electrochemical impedance spectroscopy and charge-discharge study.

The prepared MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite is tested as an additive with ZnO. For this purpose, the ZnO with three different morphology is used. First, commercial ZnO nanoparticles with plate-like, spherical-like morphology. Second, ZnO nanorods synthesised by microwave heating method. Third, ZnO microrods synthesised by hydrothermal method. The solubility study conducted by atomic absorption spectroscopy shows that the one-dimensional ZnO microrods and nanorods dissolve slower in KOH electrolyte than the ZnO with plate-like and sphere-like morphology. The three ZnO materials with and without the MoS<sub>2</sub>-SnO<sub>2</sub> additive are subjected to hydrogen gas evolution, corrosion test, electrochemical impedance spectroscopy and cyclic voltammetry. The electrochemical performance of ZnO with MoS<sub>2</sub>-SnO<sub>2</sub> additive is better than the bare ZnO. Among all the samples, the performance of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods is excellent and the most suitable anode material to be used in the alkaline battery.

*Keywords: Silver nanowires; MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite; supercapacitor; ZnO nanorods; alkaline battery*

# CHAPTER 1

## INTRODUCTION

The next-generation electronic devices such as flexible displays, paper solar cells, health monitoring patches and sensors are set to meliorate the day-to-day life of the humankind (Brunetti et al. 2019) (Yuan et al. 2019). These devices will be supported by the energy storage systems like flexible thin film supercapacitors and batteries (Gao et al. 2021). These flexible electronic devices are different from the conventional electronic devices in many aspects. They are made on polymers, textiles or soft substrates, in contrast to existing devices based on the rigid substrates. They are designed to work in complex non-planar shapes to utilize the full potential of the devices and materials used in them.

### 1.1 Flexible Electronics

#### 1.1.1 Sensors

Nanogenerators can harvest electrical energy from the mechanical motions or the vibrations by the piezoelectric principle. When a piezoelectric material, such as ZnO, is subjected to mechanical deflections, there will be flow of electrons. The ZnO nanowires could be integrated into wearable devices to monitor human health by their body movements (Panth et al. 2020). This can be mounted on a moving part of a human body and can also charge portable devices, such as mobile phones (Thakur et al. 2018).

#### 1.1.2 Optoelectronic devices

The solar cell is an optoelectronic device, is a future system for green energy generation. The commercial silicon solar cells can only be used as planar-shaped panels as the materials used in them are primarily brittle. The organic solar cells (OSC) are the potential technology devices for the future as these are flexible systems and can be used in any shape (Reddy et al. 2017). Such cells can be used in roofs, windows or even on clothes to charge the portable/wearable devices.

Another optoelectronic device is the light-emitting diode (LED). Like OSCs, organic LEDs (OLED) are flexible. These can be rolled as paper and put into the pocket. Also, they can be used in touch screens and wearable devices, like smart watches (Fukagawa et al. 2018).

### **1.1.3 Film heaters**

The transparent conductive film based heaters are used to defrost/defog the front panels of aircraft, automobile windshields and wearable devices (Tiwari et al. 2017) (Lee et al. 2020). The film heaters are also used as thermography patches to treat arthritis-related illness (Sharma et al. 2020).

## **1.2 Transparent Conductive Materials**

The transparent conductive electrode (TCE) is an essential element in the devices mentioned above. The indium tin oxide (ITO) is the most widely used TCE material in OSCs and OLEDs. It has excellent optical transparency (more than 95 %) and low-sheet resistance (5-10  $\Omega$ /sq). ITO is a brittle metal oxide. The mechanical flexibility, a critical property for any flexible devices, is limited in the devices that use ITO as the TCE (Chen et al. 2001). Also, the cost of the material is high because of the low abundance of indium. Therefore, there is a need for an alternative material to replace high-cost, brittle ITO to develop sustainable flexible devices.

Low-sheet resistance, high optical transparency and mechanical flexibility are the critical properties for a flexible transparent conductive film. Graphene, carbon nanotube (CNT), metal nanowires have been explored to replace the ITO. Single-layer graphene is a promising candidate, but synthesis of single-layer graphene using the chemical vapor deposition (CVD) technique is expensive. Graphene produced by the exfoliation of graphite is not uniform and has poor electrical properties. Similarly, CNT grown from the CVD route has high junction resistance between the nanotubes. There are metal nanowires (NWs) mesh electrodes made up of copper and silver. Copper (Cu) is a more abundant material than the silver (Ag). But the optical transparency (93 %) and lower sheet resistance (20  $\Omega$ /sq) of Ag NWs based electrodes (Chang et al. 2014) are

too far to reach by Cu NWs based electrodes. It has an optical transparency of 85 % and sheet resistance of 31  $\Omega$ /sq (Zhang et al. 2020a).

### **1.2.1 Silver nanowire electrode**

The TCE films fabricated using silver nanowires show excellent transparency and low sheet resistance close to ITO. The optical transparency and electrical conductivity of the Ag NWs film depend on the length and diameter of the nanowires and the density of nanowires in the film. The Ag NWs film can reach 93% transparency with a sheet resistance of less than 20  $\Omega$ /sq. The mechanical flexibility of Ag NW film is excellent when compared with the ITO and fluorine-doped tin oxide (FTO). The Ag NW film retains its lower sheet resistance even after many bending cycles (Langley et al. 2013). It can be bent to a bending radius of 5 mm without any loss in electrical conductivity.

### **1.2.2 Problem of oxidative blocking/etching in the synthesis of Ag nanowires**

The one-dimensional growth of the silver nanowires is often hindered by oxidative blocking or etching of silver seed particles during the polyol synthesis process (Wiley et al. 2004). Wiley et al. (2005) and Korte et al. (2008) reported that the introduction of Fe(II)/Fe(III) and Cu(I)/Cu(II) ions during the synthesis process prevented this oxidative blocking of silver seeds and enhanced the growth of silver nanowires. Due to their dual oxidative states, copper and iron are proven to remove the oxygen from the silver seeds through the redox process. Amongst copper and iron, the copper ions showed better results than the iron ions (Bob et al. 2016) (Ma and Zhan 2014). However, the silver nanowires synthesised in the presence of Cu(II) tend to have large diameters, in the range of 125-250 nm (Bob et al. 2016).

Many efforts are put to improve the aspect ratio (length to diameter) of the silver nanowires. Some of them are multistep synthesis (Li et al. 2015), replacing the small chain length PVP molecules with the longer chain PVP molecules (Sonntag et al. 2019), the addition of Br<sup>-</sup> ions (Zhang et al. 2018a), synthesising in high pressure (Zhang et al. 2017b) and N<sub>2</sub> gas environments (Niu et al. 2018) along with the use of oxygen scavengers, like copper or iron ions. Despite the improvements achieved by tailoring

other parameters, the presence of oxygen scavengers (like Cu/Fe ions) remains crucial in the synthesis of silver nanowires (Zhang et al. 2019).

### **1.3 Flexible Batteries**

The wearable devices have to be incorporated with an energy storage device to ensure continuous supply of the electrical energy. The bio-integrated devices which monitor body movements and blood pulse will experience compression, bending and twisting deformations (Berchmans et al. 2014).

#### **1.3.1 Available battery cells**

Lithium-ion batteries are the current leaders in battery domain. These batteries are attractive due to their high open-circuit voltage, low self-discharge and lack of memory effect. But there are many problems along with these merits. The use of hazardous non-aqueous solvents, the need for careful encapsulation to protect these materials from the environmental contact are some of the demerits (Wang et al. 2012). The issues of safety problems and low specific energy ( $150 \text{ Wh Kg}^{-1}$ ) increase concerns when used in wearable human-interface devices and underwater applications.

The zinc alkaline batteries like Zn-Ag, Zn-Ni, Zn-Mn and Zn-air are used in many electronic systems ranging from wrist watches to missiles, space and underwater equipments. Unlike lithium-ion batteries, zinc alkaline batteries have the following favourable characteristics (Karpinski et al. 1999),

- Very high specific energy (up to  $1084 \text{ Wh kg}^{-1}$ ) and volumetric energy density (up to  $750 \text{ Wh dm}^{-1}$ )
- High rate discharges and linear voltage over the entire range of its discharge
- Low self-discharge rate (5% per month)
- Safe and environmentally friendly system

As the Zn alkaline batteries are safe and reliable, they can be used to power the wearable devices (Huang et al. 2019b).

### 1.3.2 Working principle of Zn-Ag battery

The charging and discharging of a zinc-silver battery may be represented by a single reversible equation given below (Eqn. 1 and 2). The anode and cathode are made up of zinc (Zn) metal and silver oxide (Ag<sub>2</sub>O), respectively. The aqueous solution of salts LiOH, NaOH and KOH are used as the electrolyte in such batteries. But the KOH solution is widely used as the electrolyte because of its high ionic conductivity. The OH<sup>-</sup> anions in the electrolyte act as the charge carriers during the electrochemical cycle (Berchmans et al. 2014).

During discharging, the silver oxide is reduced to silver and the zinc is oxidized to zinc oxide (ZnO). The chemical process is reversed during charging after the cell has been discharged. The oxidation and reduction reactions of Zn anode are the same in other Zn alkaline battery systems, such as Zn-Ni, Zn-Mn and Zn-air.

### 1.3.3 Limitations of Zn alkaline batteries

#### 1.3.3.1 Dissolution of the Zn anode material

High dissolution rate of the Zn/ZnO material in the highly corrosive alkaline electrolyte (KOH) is one of the significant factors for the short lifetime of Zn alkaline batteries. During discharge, the Zn metal is converted into Zn(OH)<sub>4</sub><sup>2-</sup> ions. These zincate ions slowly dissolve into the electrolyte solution (Mainar et al. 2018b). When the electrolyte near the anode is saturated with the zincate ions, the zincate ions precipitate into compact irreversible ZnO on the anode. A layer of thick ZnO passivates the active

anode particles (Mainar et al. 2018a). The cycle life and reversibility of the battery are reduced due to the dissolution and passivation of the Zn/ZnO anode.

### ***1.3.3.2 Dendrites growth***

The high dissolution of zincate ions causes another problem of dendrite growth in the anode. During the charging process, the zincate ions are reduced back to metallic Zn. This process is called Zn plating. The local dissolution of Zn and concentration differences lead to the non-uniform deposition of Zn. This non-uniform deposition is the reason for the shape change and the dendritic growth. The dendrites continue to grow and pierce the separator. This leads to a short circuit of the anode with cathode causing failure of the battery. Also, the change in shape decreases the active surface area of the anode material (Ozgit et al. 2014).

Figure 1.1 SEM micrograph shows the dendrite formation on Zn electrode (Ozgit et al. 2014)

### ***1.3.3.3 Evolution of hydrogen gas***

The evolution of hydrogen ( $H_2$ ) gas is due to the undesirable water electrolysis reaction during the charging process. The evolution of  $H_2$  gas would lead to increase in the internal pressure of the battery, loss of water in the electrolyte and corrosion of the Zn/ZnO anode that produces  $Zn(OH)_2$  (Turney et al. 2017) (Mainar et al. 2018a).

Hence, the present study focuses on transparent conductive silver nanowires film and Zn anode for the alkaline battery. The study aims to synthesis uniform, longer and high aspect ratio silver nanowires in the presence of different oxygen scavengers. The

fabrication and characterization of transparent conductive silver nanowires film are also discussed. The present study also investigates the effect of size and morphology of the ZnO anode on their electrochemical performance in the KOH electrolyte. The preparation and analysis of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite as the additive to the ZnO are also discussed. The details of the study are represented in this thesis as different chapters. The review of relevant literature is presented in chapter two. The experimental details on synthesis, fabrication and various characterization techniques are given in chapter three. The results and discussion on transparent conductive silver nanowires film are presented in chapter four. Chapter five and six discusses the synthesis and characterization of MoS<sub>2</sub> nanosheets and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite, respectively. The results of the ZnO anode are discussed in chapter seven. The inferences of the present study are summarised in chapter eight. After the list of references, the publications based on this study are listed.

## CHAPTER 2

### LITERATURE REVIEW

*The literature reviews on the synthesis, characterization and applications of transparent conductive silver nanowires, ZnO anode for alkaline battery, MoS<sub>2</sub> nanosheets and tin oxide nanoparticles for energy storage applications are presented in this chapter.*

#### 2.1 Review on Silver Nanowire Transparent Conductive Electrodes

Silver nanowires (Ag NWs) are prepared by different routes. Filling the silver metal into the carbon nanotubes (Govindaraj et al. 2000), use of co-polymers to form silver aggregates to grow into wires (Zhang et al. 2001) and electrochemical deposition of the silver into the pore of anodic alumina membrane (AAM) (Zong et al. 2004) are some template-based methods to synthesis silver nanowires. Ag NW is also produced by the polyol method by using the reduction reaction of silver nitrate by the ethylene glycol. The poly (vinyl pyrrolidone) (PVP) act as a capping agent (Sun et al. 2002a). The dimensions of the nanowires produced by the template route were limited to the template dimension. The nanowires produced by this method often form into aggregate bundles. The additional process to remove the template from nanowires adds up with forementioned drawbacks to look into other easier routes for silver nanowire synthesis. On the other hand, the polyol process does not have any such problems and it is a convenient route to produce the Ag NWs on a large scale.

##### 2.1.1 Polyol synthesis of silver nanostructures

Silver nitrate (AgNO<sub>3</sub>) is used as the silver source in the polyol method. Ethylene glycol is used as the solvent and reducing agent for the silver nitrate. Poly (vinylpyrrolidone) (PVP) is used to act as the capping agent. The experiment is conducted in a round bottom flask under magnetic stirring in a heated oil bath. The Ag<sup>+</sup> ions from the AgNO<sub>3</sub> get reduced to form silver nanoparticles and they continue to grow into large particles by Oswald ripening. PVP agent passivates some of the facets of these particles and thus controls the growth in a particular direction (Coskun et al. 2011).

The  $\text{Ag}^+$  ions from the  $\text{AgNO}_3$  solution are reduced by ethylene glycol when it is introduced into the heating flask (Figure 2.1). This leads to the formation of silver nuclei (step I). These nuclei grow and reach critical size (step II). Because of the available thermal energy associated with these nuclei, the structure fluctuates and allows defects to form (Baletto and Ferrando 2005, Wiley et al. 2007). The twin boundary defects are preferred to form due to the low surface energy.

Figure 2.1 Growth of silver nanostructures (Wiley et al. 2005)

With respect to the reduction rate of  $\text{Ag}^+$  ions, single crystal seed, multiply twinned with 5-fold decahedron and quasi-sphere defects are formed (Wiley et al. 2005).

### 2.1.2 Growth mechanism

Earlier, it was mentioned that the thermal energy fluctuations during the nucleation stage lead to the formation of twin defects to lower the surface energy. These twins act as the seeds for the growth of the nanostructures. Amongst all twin seeds (crystal, single twin, multiple twins), multiply-twinned decahedra are the most stable seed, as it is bound by  $\{111\}$  facets. Therefore, it is the most abundant seed for the growth of silver nanostructures.

Figure 2.2 Growth mechanism of a silver nanowire (Sun et al. 2003)

Figure 2.2 (A) explains the evolution of a nanorod from a multiply twinned nanoparticle (MTP) of silver under the confinement of five twin planes and with the assistance of PVP. The ends of this nanorod are terminated by  $\{111\}$  facets, and the side surfaces are bounded by  $\{100\}$  facets. The strong interaction between PVP and the  $\{100\}$  facets is indicated with a dark-grey shaded colour (region 1), and the weak interaction with the  $\{111\}$  facets is marked by a light shaded colour (region 2). The MTP consists of five single-crystal tetrahedrons oriented radially about a central axis. All the five tetrahedrons share a common edge in the centre and each tetrahedron has two sides in contact with its neighbours. Each tetrahedron can share an angle of only  $70.5^\circ$ , leaving a gap of  $7.5^\circ$ . Significant lattice distortions, surface relaxations and defects could occur to make up for this angle difference (Wiley et al. 2004). In this case, the twin boundaries (dark lines on the end surfaces) are formed that can serve as active sites for the addition of new silver atoms. The plane marked in the dark colour (region 3) shows one of the five twin planes that can serve as the internal confinement for the evolution of nanowires from MTP. Figure 2.2 (B) is a schematic model illustrating the diffusion of silver atoms toward the two ends of a nanowire, with the side surfaces completely passivated by PVP. This drawing shows a projection perpendicular to one of the five side facets of a nanowire and the arrows represent the diffusion fluxes of silver atoms.

### **2.1.3 Synthesis of silver nanowires**

The silver nanowires were successfully synthesised (Sun et al. 2002a) by injecting  $\text{AgNO}_3$  dissolved in ethylene glycol into a preheated flask containing PVP dissolved in ethylene glycol. Then,  $\text{PtCl}_2$  dissolved in ethylene glycol was added, followed by the addition of  $\text{AgNO}_3$  solution. The Pt nanoparticles acted as heterogeneous nucleation sites for nanowires. The flask was under magnetic stirring continuously. The heating and stirring were continued till the colour of the solution became grey. This grey colour was the indication of the formation of silver nanowires.

Sun and Xia (2002) synthesised Ag NWs without Pt seeds by injecting 3 mL ethylene glycol (0.1 M) solution of  $\text{AgNO}_3$  and 3 mL ethylene glycol solution of (0.6 M) of PVP into a flask containing 5 mL ethylene glycol. The reaction was continued under magnetic stirring at 160 °C for 60 min. The final solution was washed with acetone by centrifugation to remove the PVP and undesired particles produced as the byproducts.

When silver ions are introduced into the solution, the silver ions are reduced rapidly to  $\text{Ag}^0$  state. This rapid reduction leads to the formation of silver aggregates (Hynning and Zukoski 1998). Inorganic ions, such as  $\text{Cl}^-$  or  $\text{Br}^-$  are introduced into the solution to form  $\text{AgCl}$  or  $\text{AgBr}$ . These silver halides act as the buffer phase. That ensures the controlled supply of silver species into the reaction. In this way, the chloride ions help as the electrostatic stabilizer to prevent the formation of silver aggregation and promote the one-directional growth of silver nanostructures.

### **2.1.4 Oxidative etching of silver seed particles**

As mentioned earlier, the twinned particles produced in the early stages are the seeds, for the growth of silver nanowires. During the synthesis, the molecular oxygen ( $\text{O}_2$ ) present in the reaction solution dissociates into atomic oxygen. These atomic oxygen then get adsorbed on the surface of the silver seed particles. The adsorbed atomic oxygen, to some extent, may cause the etching of these twinned particles. But, notably, they block the addition of new silver atoms to {111} reaction sites. So, the growth of the nanowires is affected by this adsorbed oxygen (Wiley et al. 2004).

### 2.1.5 Role of Fe<sup>3+</sup> and Cu<sup>2+</sup> ions

The iron ions were introduced into the reaction to prevent the twins from oxygen etching/blocking. At the reaction temperature of 148 °C, the Fe (III) ions were reduced to Fe (II) ions by ethylene glycol. The Fe (II) ions react with this atomic oxygen and get oxidized back into Fe (III) ions. This way, the oxygen was removed from the silver seeds to help the growth of silver nanowires (Wiley et al. 2005). Copper ions were used in place of iron ions as the oxygen scavenger (Korte et al. 2008) (Wang et al. 2016b). The addition of CuCl or CuCl<sub>2</sub> was effective in enhancing the growth of silver nanowires. But the diameter of the silver nanowires synthesised with the addition of copper or iron ions was more than 120 nm (Bob et al. 2016).

Figure 2.3 Oxygen scavenging from the surface of silver seed particle (Wiley et al. 2005)

Recently, researchers used Co<sup>2+</sup> ions and Cr<sup>2+</sup> ions as the oxygen scavengers in place of Fe<sup>3+</sup> and Cu<sup>2+</sup> ions (Abbasi et al. 2016) (Zhang et al. 2019).

### 2.1.6 Process parameters

In polyol synthesis, the process parameters such as PVP/AgNO<sub>3</sub> ratio, reaction temperature, amount of NaCl, injection rate of AgNO<sub>3</sub> precursor and solution stirring rate play essential roles in quality of the final product (Coskun et al. 2011).

### **2.1.6.1 Reaction temperature**

The reaction temperature should be high enough for ethylene glycol to convert into glycolaldehyde which reduces  $\text{Ag}^+$  ions to Ag atoms.

This is possible only if the temperature is above 150 °C and with the aid of oxygen (Coskun et al. 2011). At 110 °C, microns-sized Ag particles are produced instead of the rod or wire structure (Sun et al. 2002b). If the temperature is between 130 °C to 150 °C, the twins start to nucleate and a rod-like shape is formed (De Oliveira et al. 2013). At 170 °C, enough thermal energy is available to produce the multiply twinned particles that grow into nanowires. At higher temperature (190 °C), the thermal energy available for twin formation is excess than the required. So, the nanowires which are formed at the beginning stage grow longer. But short nanowires are also produced in the later stage due to the reduced silver quantity in the reaction solution.

### **2.1.6.2 PVP/AgNO<sub>3</sub> molar ratio**

If the ratio of PVP/AgNO<sub>3</sub> is small, there would be insufficient PVP molecules to passivate the {100} faces of twinned particles. That will lead to the addition of silver atoms to {111} facets, {100} facets and other facets. The micron-sized particles are produced as the result (Coskun et al. 2011). Otherwise, the reaction produces large diameter silver nanowires (Jiu et al. 2009). Both are not desirable. If the ratio is high, the excess PVP molecules will cover {111} faces and block the addition of silver particles. Hence it results in the formation of silver particles (Sun and Xia 2002) or very short silver nanowires. So the optimum molar ratio should be taken to synthesise the nanowires (Sun et al. 2002b). Different shapes such as nanocubes, spheres, nanowires, plates can be produced by changing the PVP/AgNO<sub>3</sub> molar ratio (Wiley et al. 2005).

### **2.1.6.3 Molecular weight (MW) of PVP**

The molecular weight (molecular chain length) of the PVP molecules also influences the growth and yield of the silver nanowires. The earlier works on the synthesis of silver nanowires used PVP (K30) with MW of 40,000-55,000 (Sun et al. 2002b, Gao et al.

2005). Zhu et al. (2011) reported that increasing the MW of PVP would result in a high yield of nanowires without many particles. When the PVP of MW 800,000 was used to synthesis the silver nanowires, the yield of silver nanowires was very high. Also, the length of the silver nanowires increased from 3  $\mu\text{m}$  to 10  $\mu\text{m}$ , due to the chemical adsorption of  $\text{Ag}^+$  ions on the chains of the PVP molecules. Zeng et al. (2014) synthesised silver nanowires using PVP with different molecular weights (chain lengths). Only silver nanoparticles and short rods were produced when the PVP of low molecular weight was used. But, the silver nanowires were produced when the molecular weight of the PVP used was more than 40,000. Da Silva et al. (2016) reported that the PVP with MW 1,300,000 yielded high silver nanowires having a diameter of less than 20 nm. As the chain length (molecular weight) of the PVP molecules increases, the interaction of PVP molecules on the {100} facets of silver nanowires becomes stronger. This results in effective passivation of {100} facets to limit the addition of the new silver atoms in the lateral direction.

#### ***2.1.6.4 Amount of NaCl***

The role of chloride ions on the growth of silver nanowires in the polyol method is discussed earlier. The chloride ions prevent the aggregation of silver particles by forming a buffer phase of AgCl that supplies silver atoms to the reaction in a controlled manner. If the concentration of chloride ions is high, it would produce large AgCl particles (Coskun et al., 2011) or it would etch the twin particle to form silver particles (Wiley et al., 2004). Another result reported that increase in the chloride ions (within the optimum chloride ions concentration range), leads to decrease in the diameter of silver nanowire (Chang et al., 2011).

#### ***2.1.6.5 Use of bromide salts***

The bromide salts such as NaBr or KBr are used as the electrostatic stabilizers, like NaCl. Similar to  $\text{Cl}^-$  ions, the  $\text{Br}^-$  ions react with the silver ions and form the AgBr phase to avoid the formation of silver aggregation. But the use of the  $\text{Br}^-$  ions reported to yield nanowires with a smaller diameter than that synthesised with  $\text{Cl}^-$  ions (Zhang et al. 2015). Also, like PVP molecules, the  $\text{Br}^-$  ions interact more with the {100} facets of the silver nanowires than with the {111} facets. So, the {100} facets are passivated by the

Br<sup>-</sup> ions. Due to this passivation of {100} facets against the addition of silver atoms, the silver nanowires with small diameters are produced (Zhang et al. 2018a).

#### ***2.1.6.6 Presence of organic solvents and salts***

As mentioned earlier, the Br<sup>-</sup> ions adsorbed onto the {100} facets of silver limit the addition of silver atoms in the lateral direction. But the Br<sup>-</sup> ions desorb from the silver surface due to the high reaction temperature during the synthesis process. Niu et al. (2018) explored benzoin as the reducing agent in the synthesis of silver nanowires. Adding the benzoin and the NaBr helps to bring down the reaction temperature required for the reduction of Ag<sup>+</sup> to Ag<sup>0</sup>. At this relatively lower temperature, the adsorption of Br<sup>-</sup> ions onto the {100} facets of silver surfaces is increased. The increased passivation of {100} faces by the Br<sup>-</sup> ions resulted in the growth of silver nanowires with a small diameter.

The addition of ionic liquids, such as tetrapropylammonium chloride, tetrapropylammonium bromide helps to reduce the diameter of silver nanowires (Chang et al. 2014). The mentioned salts are composed of ammonium<sup>+</sup> cations and Cl<sup>-</sup> and Br<sup>-</sup> anions. The halide anions formed AgCl and AgBr phases that controlled the nucleation of silver particles. The ammonium<sup>+</sup> cations acted as the size-controllable template for the growth of silver nanowires. Jang et al. (2018) used tetrabutylammonium dichlorobromide salt in place of regular halide salts. The silver nanowires with a diameter of 32 nm were synthesised. It was reported that the diameter of the silver nanowires could be varied by changing the salt concentration or type of the salt used.

#### ***2.1.6.7 Solution stirring rate***

The stirring during the synthesis ensures that the concentration of Ag<sup>+</sup> ions is uniform throughout the solution. If the stirring speed is very slow, the local concentration of Ag<sup>+</sup> ions will be high in some regions, leading to the aggregation of silver particles. If the stirring rate is high, it results in thin and short nanowires. Therefore, the stirring should be sufficiently low to ensure the addition of silver atoms onto twinned particles and facilitate the growth of long nanowires (Lee et al. 2012).

### **2.1.7 Synthesis environment**

The silver nanowires were synthesised in a high-pressure environment by the hydrothermal method (Jang et al. 2017). The pressure-controllable autoclave was used to synthesis the silver nanowires. The diameter of the nanowires was reduced with increase in the pressure. The silver nanowires with 15 nm diameter were produced at the pressure of 190 psi. At high pressure, the nucleation rate of silver seed particles increased. This spontaneous nucleation resulted in the formation of small-size silver particles which eventually grew into small diameter nanowires.

Azani and Hassanpour (2019) synthesised the silver nanowires by solvothermal method at a pressure up to 200 psi along with nitrogen gas purging. The synthesised silver nanowires showed a mean diameter of 17 nm. Hence, it is concluded that the synthesis of silver nanowires at high pressure and in an N<sub>2</sub> gas environment would result in small diameter nanowires.

### **2.1.8 Separation of silver nanowires**

The silver product synthesised by the polyol method contains silver nanowires and undesired silver nanoparticles. These particles should be removed along with the PVP molecules and ethylene glycol solvent used for synthesis. The centrifugation technique was used to separate the silver nanowires from particles and wash away the PVP and ethylene glycol. The synthesised product was first diluted with acetone (1:5 to acetone). Then the diluted solution was centrifuged at 2000 rpm for 20 min (Sun and Xia 2002). The supernatant contains particles and other chemicals which was removed. Then obtained sediment/precipitate was washed with isopropyl alcohol (IPA) by centrifugation process, like in the previous step. This washing was repeated further for three more cycles. Finally, the purified silver nanowires was dispersed in isopropyl alcohol to fabricate the transparent conductive films (De et al. 2009).

## **2.1.9 Preparation of silver nanowire films**

### ***2.1.9.1 Drop casting***

The drop-casting is a simple technique to produce the silver nanowires transparent conductive film. The known concentration of a solution with silver nanowires was taken in a pipette and dropped onto a glass or any flexible substrate (Tokuno et al. 2011). The patterned coating was made by taping a patterned polyimide tape on the substrate and dropping the nanowire solution. The patterned silver nanowires films could be obtained by removing the polymer tape (Amjadi et al. 2014).

### ***2.1.9.2 Meyer rod method***

The transparent conductive silver nanowires electrode film was prepared by Hu et al. (2010) using the Meyer rod coating method. A few drops of silver nanowires solution were dropped on to the substrate and the rod was rolled over to spread the nanowires solution uniformly on the substrate. The film thickness of 4-60  $\mu\text{m}$  was prepared by changing the concentration of the solution. Zhu et al. (2013) prepared the silver nanowires transparent conductive electrode by using Meyer rod method. During the coating, the substrate was kept on a hot plate of 92 °C to evaporate the solvent from the solution immediately.

### ***2.1.9.3 Vacuum filtration***

De et al. (2009) prepared silver nanowires film by vacuum filtering the silver nanowires solution using the cellulose ester membrane. The deposited nanowires on the membrane were transferred to polyethylene terephthalate (PET) substrate by heating and pressing. The PET substrate was placed on a hot plate kept at 100 °C. The membrane was placed on PET to make contact and a 3 kg weight was placed over it for 2 hours. Then the membrane was removed by acetone treatment. Lee et al. (2012a) also prepared a flexible silver nanowires film by the same vacuum filtration method but with the Teflon membrane.

#### ***2.1.9.4 Spin coating***

The silver nanowires films were prepared by adding the drops of the nanowires dispersion on the substrate fixed on a rotating disk. At higher speed, the solution spread out more to produce the less dense and more transparent film. At a lower speed, a denser and less transparent film is produced. Spechler and Arnold (2012) prepared the silver nanowires film by spin coating by adding nanowires dispersion till the transparency of the film became 65%.

Nam et al. (2014) fabricated the flexible transparent conductive films by spin coating silver nanowires dispersion on glass and Si substrate for 40 sec. Different films were prepared by changing the spin speed between 600-3000 rpm. Then, the obtained silver nanowires films were annealed at 100 °C for 5 min. A commercial ultraviolet curable polymer, 'Norland Optical Adhesive (NOA) 63' was spin-coated on the prepared silver nanowires film and cured by UV irradiation. Finally, the Ag NWs/NOA 63 film was peeled off from the glass substrate to get flexible Ag NWs film. Hwang et al. (2015) used poly-dimethylsiloxane (PDMS) instead of NOA 63 to obtain the flexible Ag NWs film.

#### ***2.1.9.5 Spray coating***

The spray coating is another technique to fabricate the silver nanowires films. The Ag NWs dispersion is sprayed on the substrate using the commercial air-brush spray gun (commercial air-brush) with an air compressor. Yang et al. (2011) used this spray-coating method to prepare the transparent conductive Ag NWs film. The pre-treated PET substrate was taped on a large glass plate kept on a hot plate at 130 °C. Then the film was held between two aluminium plates and pressed. Choi et al. (2013), Abel et al. (2014) and Coskun et al. (2013) had used this spray-coating method to fabricate the Ag NWs film but with hot plate temperatures of 60 °C, 130 °C and 150 °C, respectively.

#### **2.1.10 Post-film treatment**

There are a few problems associated with the silver nanowires films fabricated by any one of the above coating methods. As the silver nanowires are randomly arranged on the substrate, the surface roughness of the Ag NWs would be considerably high to cause

short-circuit by penetrating the thin layer of solution-processed polymer blends atop the Ag NWs electrode (Lee et al. 2008). Hu et al. (2010) reported that the mechanical pressing of the Ag NWs film after the coating decreased the surface roughness.

The capping agent (PVP) used to synthesis the silver nanowires remains as a layer around the nanowires. Tokuno et al. (2011) conducted an experiment on the effect of the PVP layer on the electrical resistance of silver nanowires film. The sheet resistance of  $6.9 \times 10^6 \Omega/\text{sq}$  was observed in the as-prepared film. So, the PVP molecules present on the silver nanowires need to be removed to obtain a good conductive silver nanowires film. Lee et al. (2008) experimented with comparing the sheet resistance of silver grid film and silver nanowires film. They found out that the silver nanowires film showed higher sheet resistance than the silver grid. The resistance at the nanowires junction was the reason for this higher resistance. Annealing the silver nanowires film helps to remove the PVP molecules present in the film and decreases the junction resistance by fusing the nanowires at the junctions. The heat-treatment of silver nanowires film at 200 °C for 20 min removed the PVP molecules from the silver nanowires and fused the nanowires junction to decrease the sheet resistance of the silver nanowires film (Tokuno et al. 2011).

### **2.1.11 Properties of silver nanowire electrodes**

#### ***2.1.11.1 Electrical properties***

The electrical resistance of the silver nanowires network is higher than the bulk silver due to the surface scattering of electrons. Bid et al. (2006) studied and reasoned this phenomenon. If the diameter of the nanowire is close to or below the mean free path of electrons in bulk material, the effect of electron scattering increases the resistance of the individual nanowires. The length of the nanowires also contributes to the electrical properties of the silver nanowires film.

Figure 2.4 Effect of length and diameter of silver nanowires on the sheet resistance and transparency of the film

Hecht et al. (2006) explained this with carbon nanotubes but it can also be applied to silver nanowires network. In this model, it was explained that with longer nanowires, the conductive path (percolation path) is achieved with minimum number of nanowires. This decreases the nanowires junctions and thus lowers the sheet resistance of the film.

### 2.1.11.2 Electro-optical properties

The density of silver nanowires affects the optical transparency and the sheet resistance of the silver nanowires film. If nanowires density is high, there are more nanowires available to make the path for electrical conductivity. On the other hand, increasing the density of the nanowires will decrease the optical transparency of the film (De et al. 2009). Sonntag et al. (2019) synthesised silver nanowires of different lengths and diameters by varying the molecular weight of the PVP. The transparent conductive silver nanowires films were fabricated by the spray coating method. The silver nanowires film with the optical transparency of 85.5% and sheet resistance of 24.4  $\Omega/\text{sq}$  was achieved using the silver nanowires with a mean length of 20  $\mu\text{m}$  and mean diameter of 66 nm. Xu et al. (2018) fabricated the silver nanowires films by spin coating. The silver nanowires film showed more than 90% optical transparency and the sheet resistance less than 10  $\Omega/\text{sq}$ . The high transparency and low sheet resistance were achieved due to the longer silver nanowires and cold-welding at the nanowires junctions.

### ***2.1.11.3 Thermal properties***

Thermal annealing is vital to improve the electrical properties of silver nanowires films. It helps to decrease the sheet resistance of the film. This annealing process removes unwanted excess material, such as PVP polymer molecules from the surface of the nanowires. Also, it induces local welding at the nanowires junctions which further decreases the sheet resistance of the film. Although the thermal annealing process improves the electrical conductivity, the silver nanowires film starts to fail when the annealing temperature is increased above 300 °C. When the annealing temperature exceeds the thermal limit, the silver nanowires becomes unstable. This is called as Plateau-Rayleigh instability (Langley et al. 2013). The nanowires break into the small spheres-like structure, thus causing the failure of the nanowires network (Langley et al. 2014). This phenomenon is called as spheroidisation.

### ***2.1.11.4 Mechanical properties***

As silver nanowire is made up of metal, it will show excellent mechanical properties such as compression, tension or torsion strength. Langley et al. (2013) compared the sheet resistance of Ag NWs film, ITO and FTO after the bending test to test the mechanical stability. The increase in the sheet resistance of ITO and FTO films was much larger than that of the silver nanowires film. Kang et al. (2013) reported the change in sheet resistance against the bending angle for Ag NWs and ITO films. The sheet resistance of ITO film increased significantly when the bending radius was reduced to 15 mm. But, the sheet resistance of Ag NWs film was not changed up to a bending angle of 5 mm.

### **Critical review on transparent conductive silver nanowires film**

*The silver nanowires are conventionally synthesised by the polyol method using silver nitrate as the silver precursor, PVP (MW=40,000-55,000) as the capping agent and NaCl as the electrostabilizer to promote the one-directional growth. The silver nanowires transparent conductive electrode (TCE) is fabricated by spray coating or spin coating or vacuum filtration methods using the synthesised silver nanowires. The transparent conductive silver nanowires film having the optical transparency of more*

than 90% and sheet resistance of less than 10  $\Omega/\text{sq}$  are achieved. The optical transparency and the sheet resistance could be tailored by changing the dimensions of the nanowires and the coating parameters. The diameter of the nanowires could be reduced by the addition of  $\text{Br}^-$  ions, use of high molecular weight PVP, optimising the PVP/ $\text{AgNO}_3$  ratio and high-pressure synthesis environment. The length of the nanowires is often affected by the atomic oxygens adsorbed on the surface of the silver seed particles. The ions of iron, copper and chromium are explored as the oxygen scavengers to remove the oxygen from the surface of the seed particles to enhance the length of the silver nanowires. But the diameter of the silver nanowires is large when the iron or copper ions are used during the synthesis.

## **2.2 Review on the Zn/ZnO Anode Materials**

The rechargeability and recyclability of the Zn/ZnO anode could be improved by controlling the dissolution of anode in the alkaline electrolyte, suppressing the hydrogen evolution and enhancing the charge transfer between electrode and electrolyte. The efforts are made to improve its electrochemical performance by tuning the morphology of Zn/ZnO anode and adding external additives with the Zn/ZnO anode material

### **2.2.1 Improvements in Zn/ZnO morphology**

#### **2.2.1.1 Layered double hydroxides (LDH)**

The layered double hydroxides (LDH) are stacked with cationic metal hydroxide layers with anions in the interlayers as the charge neutralizers. There are notable advantages, like feasibility of intercalating the structure with different anions, accommodating divalent and trivalent cations into LDH. These advantages make them as attractive materials to use for energy storage applications (Vialat et al. 2015). Fan et al. (2013) developed ZnAl-hydrotalcite LDHs by coprecipitation method as an anode material for the Zn-Ni alkaline battery. The ZnAl-hydrotalcite showed better electrochemical activity in terms of cyclic stability and reversibility compared to the Zn powders. It was attributed to the lamellar structure and aluminium ions. The aluminium played a key role in restricting dendrite growth by aiding in zinc nucleation during the deposition

process. However, the Zn/Al-LDH based anode performance was limited by their low conductivity that affects electron transportation.

Additives like carbon nanotubes (CNTs) (Yang and Yang 2013), silver nanoparticles (Yang et al. 2014b) and two-dimensional graphene sheets (Long et al. 2017a) were used with Zn/Al-LDHs to improve its conductivity and to facilitate the electron transportation. The enhanced electronic conductivity achieved by the conductive additives resulted in better charge-discharge performance with good cycle stability.

### ***2.2.1.2 Nanorods***

Yuan et al. (2005) synthesised ZnO nanorods and ZnO nanoparticles with prism shape by using the chemical vapor deposition process. These synthesised materials were used as the anode for the Zn-Ni battery to study the effect of ZnO morphology on its electrochemical performance. The study revealed that the nanorods are more stable than nanoparticles with prismatic morphology. The nanoparticles become compact after long charge-discharge cycles that reduced their electrochemical activity.

Ullah et al. (2013) studied the solubility of the ZnO in the alkaline electrolyte with microparticles and one-dimensional rods (length  $>5 \mu\text{m}$ , diameter = 450 nm). The one-dimensional ZnO rod showed better stability in 6 M KOH solution than the ZnO microparticles. The dissolution of material at edges and corners were avoided in the case of ZnO rods that resulted in low solubility of ZnO. Also, the ZnO rods with 450 nm diameter offered more surface area than the microparticles. The surface area and low solubility of the ZnO anode resulted in improved capacity and longer cycles.

Kwak et al. (2017) reported the performance of hexagonal ZnO microrods (diameter =  $5 \mu\text{m}$ , length =  $15 \mu\text{m}$ ) in LiOH, NaOH and KOH electrolytes. The electrochemical activity of the ZnO microrods determined from the cyclic voltammetry was high with the KOH electrolyte. The voltage difference between the charge and the discharge process was narrow which indicates the low voltage loss.

### ***2.2.1.3 Nanoflakes and nanoplates***

Ma et al. (2008) synthesised ZnO of plate-like morphology by following hydrothermal method. The synthesised ZnO nanoplates were 200 nm to 500 nm in width and 50 nm of thickness. The ZnO nanoplates and conventional ZnO with hexagonal prism morphology were used as the anode material in the Zn-Ni battery. The ZnO plate-like structure converted into a spindle-like structure with a smooth tip after 67 cycles of charge-discharge. But, the conventional ZnO with hexagonal prism structure changed to a sharp-tipped dendritic structure after 67 cycles.

Im et al. (2016) studied the electrochemical performance of ZnO with nanoplate (L=300nm, W=250 nm, t=50 nm), nanobead (L=500 nm), nanorods (L=500 nm) morphology and compared their performance with ZnO cubic morphology. The cyclic voltammetry study revealed that the electrochemical activity of nanoplates and nanorods was higher than that of the nanobeads and conventional cubic particles. The charge-discharge results of the fabricated Zn-Ni battery showed that nanoplates and nanorods possess high capacity retention. After 30 cycles, the nanoplate structures changed into cotton ball structures. The ZnO nanorod morphology changed into small needle-like structures, whereas ZnO nanobeads and ZnO cubes were grown into a dendrite structure.

Yan et al. (2018) used ZnO nanoplate synthesised on the graphene sheets as the anode. This ZnO/graphene showed low electrochemical resistance, excellent charge transfer and uniform deposition during the charging process. These factors helped to reduce the growth of dendrite and shape change that eventually resulted in high capacity and good cyclic stability compared to the commercial ZnO anode. The graphene acted as the platform for effective charge transfer in the anode. The as-assembled flexible Ni-Zn secondary battery retained 86% of the initial capacity of 400 charge-discharge cycles.

Liu et al. (2019) fabricated a Zn-Ni alkaline microbattery with electrodeposited Zn nanosheets as the anode. The battery performance was compared to that prepared with the Zn foil anode. The Zn nanosheet offered more surface area than the Zn foil. The nanosheets with uniform size minimized the polarization and dispersed the electric

field. The battery with Zn nanosheet exhibited high energy density, high reversibility and extended cyclic stability due to the suppressed dendrite growth.

#### ***2.2.1.4 Porous foams and sponges***

Parker et al. (2014) developed a 3D Zn sponge as the anode material for the Ag-Zn primary battery. This 3D sponge is a monolithic interconnected, continuous Zn. This ensures the long-range electronic conductivity in the anode, uniform current distribution all around the sponge, maintaining the shape/morphology of the electrode in the alkaline electrolyte by restraining the zincate ions into ZnO within an enclosed void-elements inside the porous electrode. In the case of Zn powders, the interconnectivity between the particles was lost during the discharge process. But the 3D sponge maintained its structure throughout the discharge process, thus preventing the growth of dendrites. The sponge Zn anode achieved utilization of 90% ( $728 \text{ mAh g}^{-1}$ ) during discharging in a primary Zn-air cell.

A hyper-dendrite nanoporous zinc foam was electrochemically synthesised by Chamoun et al. (2015). It was formed by a three-dimensional network of dendrites that were electrochemically active and electronically conductive at the nanoscale. The Zn foam had a conductive internal structure that caused uniform current distribution. Also, it showed to reduce the concentration gradients and polarization loss at the anode. This zinc foam showed excellent Coulombic efficiency ( $87.7 \pm 1.5\%$ ) and 100 cycles of rechargeability. The excellent performance of this Zn foam is attributed to the 3D nanoscale dendritic network and its large surface area. Davies et al. (2016) demonstrated enhanced utilization of the hyper dendrite porous Zn anode by optimizing the electrolyte concentration and different electrolyte additives. It was reported that increasing the concentration of KOH electrolyte would improve the utilization of the anode. The additives such as potassium citrate or potassium chloride showed a considerable increase in Zn anode utilization.

Wang et al. (2020) fabricated a Zn-Ni battery with the monolithic nanoporous Zn prepared by reduction-induced decomposition process, as the anode material. This nanoporous Zn anode was continuous, electronically conductive, stable in the alkaline electrolyte with high surface area and offered more charge transfer sites. During the

charge-discharge cycle, the anode undergoes coarsening controlled by surface diffusion. This coarsening helped to maintain the continuous zinc phase that resulted in its uniform reaction. That helped in preventing the progress of dendrite growth.

#### ***2.2.1.5 Microspheres***

Zhao et al. (2015) studied the ZnO microspheres (10-20  $\mu\text{m}$ ) as the anode material for the Zn-Ni battery and compared its performance with the conventional ZnO with prism morphology. The dense, compact and spherical ZnO microspheres showed good resistance against corrosion and shape change. Also, the reversibility of the ZnO microsphere anode was better than that of the conventional ZnO. The ZnO microsphere anode was activated before the charge-discharge process. The morphology of microspheres was changed into nanometer scaled ZnO rods due to the dissolution process. This reduction in particle size increased the surface area that resulted in the high electrochemical activity of the ZnO anode. After 50 cycles, it is observed that the size of the particles increased and the shape changed into a block structure.

#### **2.2.2 Additives**

The carbon based and the metal oxide based additives are used with the Zn/ZnO anode to prevent the dissolution of active zincate ions into the electrolyte, suppressing the hydrogen evolution reaction (HER) and enhancing the conductivity of the anode to improve the discharge capacity and life cycle of the battery.

##### ***2.2.2.1 Carbon based additives***

###### ***Graphene***

Ozgit et al. (2014) studied the effect of graphene sheets as an additive to the Zn anode to improve its electrochemical performance. The Zn nanoparticles (size < 50 nm) were mixed with the reduced graphene oxide (rGO) and a PTFE binder was used as the anode in a Zn-Ag battery. The added rGO improved the conductivity for charge transfer, offered a large surface area for enhanced electrode-electrolyte interaction and suppressed the dendrite formation. These factors, in turn, resulted in the increased electrochemical activity of the anode, high capacity and longer charge-discharge cycles.

Besides, the restacking issue associated with the rGO sheets was prevented by the Zn nanoparticles.

Yan et al. (2018b) reported a lasagna-inspired Zn anode, in which ZnO nanoparticles of 100 nm size were wrapped by the graphene oxide (GO) sheets. The dispersion of ZnO nanoparticles, GO and binder was cast on a polyethylene terephthalate (PET) film. Upon drying, the free-standing ZnO film was peeled off the PET. The free-standing ZnO was used as the anode material. The GO encapsulated the ZnO and it allowed only OH<sup>-</sup> ions and water to diffuse through and blocked the larger Zn(OH)<sub>4</sub><sup>-2</sup> ions that prevented the active material loss. The presence of GO in the alkaline electrolyte reduced the GO and it helped to facilitate electron transportation. Also, the GO-ZnO lasagna structure exhibited less dissolution in the alkaline electrolyte solution than the commercial ZnO. The fabricated Zn-Ni battery cells showed long charge-discharge cycles maintaining the capacity of 565 Ah kg<sup>-1</sup> for 150 cycles. The morphology of GO/ZnO lasagna anode remained unchanged even after the 150 cycles whereas the morphology of commercial ZnO particles changed entirely after 40 cycles.

### ***Carbon nanotubes***

The carbon nanotubes (CNTs) are also used as an additive to the Zn anode, like graphene sheets, to enhance the electronic conductivity of the anode. Yang and Yang (2013) prepared the composite of CNT and Zn-Al layer double hydroxide (LDH). They used it as an anode to fabricate the Zn-Ni battery. As the LDH structure gave good structural stability and controlled solubility of Zn, CNTs enhanced the electronic conductivity of the Zn-Al-LDH nanocomposite. The average discharge capacity increased as a result of improved electron transportation in the anode. The battery retained 95% of its capacity even after 200 cycles.

Cui et al. (2019) synthesised ZnO/CNT composite by the chemical filling method to use it as an anode for the Zn-Ni battery. The inner part of single-walled CNTs was filled with the ZnO nanoparticles. The electrode was prepared by adding the prepared ZnO/CNT composite with PTFE as a binder. It is reported that the contact area between CNTs and ZnO is high in this case compared to physically mixed ZnO and CNTs. It is also noted that the charge/discharge performance of the chemically filled ZnO/CNT showed poor performance at the beginning due to the low interaction of active material

with the electrolyte. The performance of ZnO/CNT composite surpassed the physically mixed ZnO and CNT anode as the number of cycle increases.

### *Conductive carbon*

Huang and Yang (2014) encapsulated the ZnO sheet-like structures with the amorphous carbon layer (thickness= 4 nm) to obtain a cellular-like structure. This cellular-like carbon-coated ZnO was used as an anode for the Zn-Ni secondary battery. The carbon coating on the ZnO enhanced the conductivity and reduced the internal resistance of the anode. The carbon-coated ZnO exhibited a lower charging voltage plateau compared to the bare ZnO. This low charging voltage would result in improved charging efficiency. On the other hand, the discharge voltage plateau of bare ZnO dropped rapidly whereas the discharge voltage remained stable for the carbon-coated ZnO. The limited dissolution of active zincate ions due to the carbon coating prolonged the discharge duration. It is reported that the discharge capacity of the carbon-coated ZnO took 25 charge-discharge cycles to reach its highest capacity. But after 16 cycles, its discharge capacity surpassed that of the bare ZnO. As the electrolyte took more time to impregnate the carbon coating, the initial capacity was less. The carbon coating suppressed the dendrite formation by preventing the dissolution of zincate ions into the electrolyte.

Chen et al. (2018) prepared a novel ZnO anode with a pomegranate structure (6  $\mu\text{m}$ ). This pomegranate ZnO was prepared via a bottom-up microemulsion approach. The ZnO nanoparticles are encapsulated by the microporous carbon framework to assemble those as secondary clusters. The small ZnO nanoparticles avoided the passivation problem since their size is much smaller than the critical passivation thickness. The microporous carbon prevented the dissolution of zincate ions into the electrolyte while allowing  $\text{OH}^-$  and water molecules to take part in the reactions. This eventually led to a high specific capacity of the anode for a longer cycle. By controlling the solubility of zincate ions, the formation of dendrite was suppressed. But it is noted that the charging voltage for pomegranate ZnO anode kept increasing for the consequent cycles. This was due to the hydrogen evolution reaction (HER) resulting from the reduction reaction of water during the charging process.

Long et al. (2017b) coated a carbon layer over sheet-like Zn-Al-Bi layered double oxide to improve the electronic conductivity. Similarly, carbon-coated Zn foil (Li et al. 2018), ZnO nanoparticles coated with carbon (Peng et al. 2019), Zn@C core-shell nanocomposite (Wei et al. 2019) and ZnO coated with nitrogen-doped carbon (Zeng et al. 2020a) are reported as the anode material. The purpose of this carbon coating over Zn/ZnO anode materials in the above reports is to 1) improve the conductivity, 2) discharge capacity, 3) preventing the dissolution of zincate ions, 4) suppress the shape change of the anode.

#### ***2.2.2.2 Metal/Metal oxide additives***

##### ***Aluminum***

The effect of aluminum oxide ( $\text{Al}_2\text{O}_3$ ) as an additive to the Zn anode was evaluated by Lee et al. (2013). A layer of  $\text{Al}_2\text{O}_3$  was coated over the Zn powders ( $52\ \mu\text{m}$ ) by chemical solution process. This  $\text{Al}_2\text{O}_3$ -Zn powder was used as the anode to fabricate a Zn-air alkaline battery. It was reported that  $\text{Al}_2\text{O}_3$  suppressed the hydrogen evolution due to its high overpotential for hydrogen evolution. Also, the  $\text{Al}_2\text{O}_3$  acted as a protection layer to prevent the Zn dissolution into the KOH electrolyte and it improved the corrosion resistance of the anode. Since the loss of Zn was minimized, the battery with  $\text{Al}_2\text{O}_3$ -Zn anode showed a longer discharging time than the one used by bare Zn powder. The self-discharge of the battery was reduced with the  $\text{Al}_2\text{O}_3$ -Zn anode as the side reaction from  $\text{H}_2$  evolution was inhibited.

##### ***Bismuth***

The influence of additives, such as  $\text{Bi}_2\text{O}_3$ , LiOH, CdO, SnO,  $\text{Ni}(\text{OH})_2$ ,  $\text{Co}(\text{OH})_2$  and alkaline earth oxides on the electrochemical performance of Zn and ZnO in the KOH electrolyte was studied by Renuka et al. (2001). The study was conducted by mixing the additives with the ZnO powder. The PTFE was used as the binder to prepare the ZnO working electrode. The  $\text{Bi}_2\text{O}_3$  showed excellent results as it enhanced the current densities from anodic and cathodic reactions. The CdO and SnO also demonstrated an excellent performance to improve the electrochemical activity of the ZnO.

Yuan et al. (2009) modified the surface of the commercial ZnO powder with  $\text{Bi}_2\text{O}_3$  coating by chemical solution method. The prepared  $\text{Bi}_2\text{O}_3$ -ZnO was used as the anode

for the Zn-Ni battery. The study reported that the surface-modified  $\text{Bi}_2\text{O}_3\text{-ZnO}$  showed stable discharge capacity for longer cycles than the bare ZnO. During the initial charging process, the  $\text{Bi}_2\text{O}_3$  undergoes an irreversible reduction reaction and became metallic Bi. This metallic Bi on the ZnO particles improved the electronic conductivity of the anode. Also, the dissolution problem of zincate ions into the electrolyte was minimized due to the passivation of ZnO by this metallic Bi layer. The improved conductivity for electron transfer and reduction of active ZnO loss attributed to high discharge capacity and longer charge-discharge cycles of the  $\text{Bi}_2\text{O}_3\text{-ZnO}$  anode.

Moser et al. (2013) investigated the role of  $\text{Bi}_2\text{O}_3$  as an additive to the ZnO with the help of in-situ X-ray diffraction measurement during charging and discharging processes. The ZnO anodes with and without  $\text{Bi}_2\text{O}_3$  were prepared to fabricate the Zn-Ni battery. During charging, the intensity of ZnO XRD peaks was reduced to Zero. Simultaneously, the Zn peak was emerged and kept increasing. That showed the reduction reaction of ZnO into Zn which is attributed to the charging process. It is noted that the intensity of the  $\text{Bi}_2\text{O}_3$  peak was reduced and the emergence of the metallic Bi peak was observed at the first charge. The conversion of  $\text{Bi}_2\text{O}_3$  into metallic bismuth led to an electronically conductive network at the nanometer scale in the anode. This enhanced the electron transportation and prevented the dissolution of zincate ions that resulted in better discharge stability for more than 50 cycles.

It is reported that the addition of  $\text{Bi}_2\text{O}_3$  does not only increase the conductivity but also influences the precipitation of zincate ions into ZnO to make it rechargeable (Shin et al. 2016). When the Zn undergoes oxidation reaction during discharging, the Zn is converted into zincate ions. These zincate ions are deposited on the surface of Bi species. Subsequently, these zincate ions are precipitated as ZnO on the surface of Bi species. The electrical contact with the ZnO was maintained due to the deposition of ZnO on the bismuth species. It makes ZnO more rechargeable for long cycles.

Many works are reported with  $\text{Bi}_2\text{O}_3$  as an additive material to improve the performance of the Zn/ZnO anode based alkaline batteries due to the advantages like improved electronic conductivity in the anode, prevention of active material (Yang et al. 2018) (Schmid and Willert-Porada 2018), etc.

But, the major drawback is heavy molecular weight of  $\text{Bi}_2\text{O}_3$  compared to  $\text{In}_2\text{O}_3$  and  $\text{SnO}_2$ . The addition of  $\text{Bi}_2\text{O}_3$  increases the weight of the anode (Shin et al. 2016).

### ***Indium***

Indium in the form of  $\text{In}_2\text{O}_3$  is used as the additive to Zn/ZnO anode to improve the electronic conductivity and to prevent anode dissolution into the electrolyte (Ma et al. 2007). Also, the addition of indium suppressed the hydrogen evolution due to its high overpotential for hydrogen evolution. Wang and Yang (2013) incorporated indium into Zn–Al layered double hydroxides (LDHs) to solve the low conductivity of LDHs problem. Like bismuth, the  $\text{In}(\text{OH})_3$  in Zn–Al–In LDH was reduced to indium metal that cannot be oxidized back due to the discharge cut-off voltage. The metallic indium formed the conductive network in the anode to facilitate electron transfer. The indium network also acted as the protective layer to minimize the dissolution of zincate ions into the electrolyte. The parasitic reaction of undesired hydrogen evolution was also suppressed due to the high hydrogen overpotential of the indium. All these benefits of indium addition led to higher discharge capacity, better stable discharge and long battery life than the Zn–Al–LDHs without indium.

Synthetic Zn–In alloy prepared by fusion of zinc and indium metal powders (0.5% and 1% In) and its electrochemical performance in the KOH electrolyte was studied with a three-electrode setup (Elrouby et al. 2021). The study concluded that the alloying In with Zn resulted in enhanced conductivity, suppressing hydrogen evolution, improved corrosion resistance and longer discharge time. The high cost of indium due to its scarcity would limit its commercial application.

### ***Silver***

The silver metal, which has high electronic conductivity, is another potential additive for the ZnO anode for alkaline battery application. Yang et al. (2014a) explored the performance of silver as an additive to the Zn–Al LDH nanosheets for a Zn–Ni battery. The surface of the Zn–Al LDH nanosheets was decorated with the silver nanoparticles. The fabricated battery exhibited high discharge capacity and good cyclic reversibility that resulted from the improved charge transfer due to the addition of silver nanoparticles. Other studies are reported using the silver as an additive to the flower-

like ZnO (Zeng et al. 2020b) and ZnO microspheres (Rong et al. 2020) to improve the electrochemical performance of the ZnO anode for the alkaline battery application.

### ***Tin***

Tin is another potential additive to the ZnO anode in alkaline batteries due to its high overpotential for hydrogen evolution (Zheng et al. 2019) and good electronic conductivity. Zhang et al. (2014) investigated the effect of SnO<sub>2</sub> on the electrochemical performance of ZnO anode in the Zn-Ni battery. The composite of ZnO/SnO<sub>2</sub> synthesised by the hydrothermal method was used as the anode. Similar to Bi<sub>2</sub>O<sub>3</sub> and In<sub>2</sub>O<sub>3</sub>, the SnO<sub>2</sub> is reduced to tin metal during the first charging process. The metallic tin formed a conductive network in the anode that resulted in better electronic conductivity. This improved conductivity decreased the charge-transfer resistance between the anode and the electrolyte. It was reported that the dissolution of ZnO was reduced due to the passivation layer formed by the tin over the ZnO surface. The hydrogen evolution was also suppressed due to the high hydrogen overpotential of tin species. The corrosion resistance of the anode was improved which is attributed to the suppression of hydrogen evolution. The discharge capacity and reversibility of the anode were enhanced by the enhanced charge-transfer between the anode and the electrolyte.

Feng et al. (2014) prepared Zn-Sn-Al LDHs as an additive to the ZnO anode. The ZnO anode was prepared by physical mixing of ZnO, Zn-Sn-Al LDHs and PTFE binder to fabricate the Zn-Ni battery. The presence of tin with Zn-Al LDHs made it an excellent additive to the ZnO. The effect was observed by the increased discharge capacity and good capacity retention for longer cycles.

### ***Titanium***

Zhang et al. (2018b) fabricated the Zn-Ni alkaline battery. ZnO was used in the form of nanorods synthesised on the conductive carbon paper. These ZnO nanorods were again coated with a thin layer of TiN by atomic layer deposition (ALD). After exposing to air, TiN was converted into TiN<sub>x</sub>O<sub>y</sub>. It was reported that the rod morphology of ZnO reduced the dissolution of ZnO into the alkaline electrolyte. In addition to that, the passivation of zinc anode by irreversible ZnO was avoided by using ZnO in the

nanometer size scale (<500 nm). The protection layer of  $\text{TiN}_x\text{O}_y$  allowed the charge transfer between the ZnO and the electrolyte but prevented the direct contact of ZnO with the electrolyte. That minimized the dissolution of ZnO into the electrolyte.

Zhao et al. (2018) coated Zn plate with  $\text{TiO}_2$  by ALD technique. This  $\text{TiO}_2$  served as the protection layer to the Zn plate to avoid direct interaction with the electrolyte. Thus, the loss of active zincate species from the Zn plate into the electrolyte was prevented. The coating of  $\text{TiO}_2$  reduced the corrosion of Zn and suppressed the hydrogen evolution due to the high overpotential of Ti. The Zn-Mn battery fabricated with this Zn/ $\text{TiO}_2$  anode maintained 85% capacity retention over 1000 cycles.

### **Critical review on Zn/ZnO anode**

*Among the various morphologies of ZnO, the nanorods, LDHs and spherical structures showed good stability in the alkaline electrolyte. The nanorods would have a larger surface area than the spherical structures. Also, the ZnO nanorods can be synthesised by following a simple hydrothermal method.*

*Carbon-based additives, such as graphene, CNTs and conductive carbon showed excellent results in enhancing the conductivity of the anode for easy charge transportation. But the issue of hydrogen evolution reaction (HER) cannot be answered by these carbon-based additives. The bismuth improved the conductivity and stability of the Zn/ZnO anode. But the specific capacity of the battery would decrease owing to its weight. The indium-based additives are the other alternative to bismuth. The low abundance of indium would increase the cost of the battery. The  $\text{SnO}_2$  would be a better additive than Bi, In, Ag and Ti based additives due to its low cost and good electrochemical properties such as suppressing hydrogen evolution and good electronic conductivity.*

### **2.3 Review on Tin Oxide for Energy Storage Applications**

Tin oxide ( $\text{SnO}_2$ ) is an n-type semiconductor material with a bandgap of 3.6 eV. The  $\text{SnO}_2$  is used in various applications such as electronics, photocatalysis, batteries and gas sensors due to its chemical and physical properties.

## **2.3.1 Applications**

### ***2.3.1.1 Electronics***

The tin oxide ( $\text{SnO}_2$ ) has high conductivity, high optical transparency and high mobility (Bansal et al. 2012). The  $\text{SnO}_2$  films are used as the transparent conductive oxide (TCO) in electrochromic devices (Kim et al. 2018). The introduction of dopant materials such as fluorine, niobium increases the electronic properties of the  $\text{SnO}_2$  (Kim et al. 2018) (Ramarajan 2019). The fluorine-doped tin oxide (FTO) is the second widely used TCO material next to ITO due to its excellent electronic and optical properties (Kim et al. 2018).

### ***2.3.1.2 Photocatalysis***

The water pollution caused by the dying industry is mainly due to the release of toxic organic dyes into the water. The polluted water is treated by photocatalytic degradation of such toxic dyes by converting or degrading into non-toxic molecules. Because of the strong oxidizing ability, low toxicity, high chemical stability and insolubility, the  $\text{SnO}_2$  is an ideal material for water treatment by photocatalysis (Al-Hamdi et al. 2017).

When a semiconductor material is excited by the incident electromagnetic radiation (ex: visible light), the  $e^-$  and  $h^+$  pairs formed (Al-Hamdi et al. 2017). The electron-hole pairs can be created in  $\text{SnO}_2$  by ultraviolet (UV) light due to its bandgap value of 3.6 eV. When UV light is illuminated, the organic dyes are converted into  $\text{CO}_2$  and  $\text{H}_2\text{O}$  by the hydroperoxyl radicals produced by the electron-hole ( $e^-$  and  $h^+$ ) pair. The pure and doped  $\text{SnO}_2$  nanoparticles or nanostructures are proved to degrade toxic pollutants such as methylene blue (Sadeghzadeh-Attar 2018), Remazol Yellow (Akti 2018), Eriochrome Black T and 2-chlorophenol (Najjar et al. 2020).

### ***2.3.1.3 Gas sensors***

Metal oxides are promising materials for gas sensor applications because of their high-affinity to gases such as CO and  $\text{H}_2$  (Al-Hamdi et al. 2017). The gas sensors are working by measuring the change in electrical characteristics of the active material caused by the adsorbed analyte gas. Due to the non-toxic nature, high chemical stability and high

conductivity, the SnO<sub>2</sub> is studied as a gas sensor material. But, the SnO<sub>2</sub> can detect the gases at high-temperature conditions only (> 200 °C) (Ingole et al. 2017). However, by engineering the grain-size, electronic structure and doping the appropriate materials, the gas sensing performance is increased while reducing the requirement operating temperature. The ultra-fine grained SnO<sub>2</sub> nanospike structures showed excellent gas sensing performance to ethanol, methanol, CO and methane (Xu et al. 2011). Also, the SnO<sub>2</sub> based gas sensors are being prepared to detect the gases, such as NO<sub>2</sub>, H<sub>2</sub>, SO<sub>2</sub> and CO<sub>2</sub> (Liu et al. 2016) (Zhang et al. 2017) (Manikandan et al. 2020).

#### **2.3.1.4 Batteries**

Graphite is the widely used anode material in commercial lithium-ion batteries because of its low cost and long life (Rothermel et al. 2016). Due to its low theoretical specific capacity of 370 mAh g<sup>-1</sup>, recent researches are focussed on the alternative material with a higher specific capacity (Chen et al. 2014). The SnO<sub>2</sub> is a potential anode material due to its higher theoretical specific capacity of 781 mAh g<sup>-1</sup> (Courtney and Dahn 1997). When SnO<sub>2</sub> is used as the anode in a Li-ion battery, the lithium ions intercalate in the SnO<sub>2</sub> structures during charging. In this process, the SnO<sub>2</sub> is irreversibly converted into Sn metal. This issue can be rectified by using the ultra-small SnO<sub>2</sub> nanoparticle or nanostructures (Chen et al. 2014). The anode fabricated using SnO<sub>2</sub> nanotubes exhibited the specific capacity of 1500 mAh g<sup>-1</sup> at a rate of 0.1 C which is higher than its theoretical capacity (Liu et al. 2014). The mesoporous structure made of ordered SnO<sub>2</sub> nanoparticles (size 9 nm) showed a capacity of 778 mAh g<sup>-1</sup> at the discharge current density of 0.1 C (Etacheri et al. 2015).

The tin oxide is also used in the zinc alkaline batteries as an additive to the Zn/ZnO anode. The addition of SnO<sub>2</sub> with the anode resulted in suppressing the hydrogen evolution reaction at the anode. The hydrogen evolution overpotential for SnO<sub>2</sub> is higher than that of the ZnO. The electrochemical performance and life of the anode are increased because of the decreased hydrogen evolution reaction by SnO<sub>2</sub> (Zhang et al. 2014).

### 2.3.2 Instability of tin oxide electrodes

There are some concerns in using SnO<sub>2</sub> as an electrode material for electrochemical energy storage applications. The volume or size expansion of SnO<sub>2</sub> during the charge-discharge (oxidation-reduction) process leads to cracks and discontinuity in the electrode, resulting in reduced capacity and life cycle (Yan et al. 2014). When the SnO<sub>2</sub> is used as the anode in lithium-ion battery, the SnO<sub>2</sub> undergoes a reduction reaction to form metal Sn during the charging process. The reduced metal Sn subsequently forms Li-S alloy with intercalated lithium ions. The dealloying of Li-S alloys happens when the battery discharges. This alloying/dealloying process leads to the size expansion of the SnO<sub>2</sub> anode. This pulverization effect impacts the cyclability of the anode negatively (Lou et al. 2006). Chung et al. (1995) observed the volume expansion of 32% when the Sn metal film was converted to SnO<sub>2</sub> by annealing in air. This volume expansion also affects the electrochemical performance of the supercapacitors fabricated using SnO<sub>2</sub> as the electrode material (Bonu et al. 2016).

### 2.3.3 Improving the stability of tin oxide

The instability of tin oxide in electrochemical applications is addressed by using suitable supportive material with it. The materials with a large surface area, good conductivity and porosity are the ideal supporting structure to improve the stability of the SnO<sub>2</sub>. The composite of SnO<sub>2</sub> and graphene oxides was prepared as the anode material for lithium-ion battery (Birrozzi et al. 2014). The active SnO<sub>2</sub> particles confined by the graphene oxide sheets have less tendency to particle agglomeration and volume expansion. Also, the large surface area offered by the graphene oxide improved the charge transfer between electrode and electrolyte.

A 3D network of porous graphene oxide/SnO<sub>2</sub> nanoparticles composite was prepared as the anode material. The porous SnO<sub>2</sub> is uniformly dispersed on the reduced graphene oxide (rGO) that served as the supportive structure to SnO<sub>2</sub>. The prepared anode shows high conductivity, large surface area with many reactive sites and porous structure to accommodate the volume expansion. The anode delivered a specific capacity of 595 mAh g<sup>-1</sup> after more than 300 charge-discharge cycles (Zhou et al. 2016). A highly conductive N-doped carbon layer was coated over the SnO<sub>2</sub> hollow nanofibers (Pham-

Cong et al. 2017). Because of the synergic effect of SnO<sub>2</sub> hollow structures and the conductive carbon layer, high specific capacity of 1648 mAh g<sup>-1</sup> was achieved.

Thus, a supporting material with a large surface area and having the ability to facilitate the charge transfer can improve the electrochemical performance of SnO<sub>2</sub> electrode in the electrochemical energy storage applications.

### **Critical review on tin oxide electrode**

*Tin oxide (SnO<sub>2</sub>) is used in many applications such as water treatment, gas sensors, electronics and batteries due to its low toxicity, chemical stability, good conductivity, and high theoretical capacity. The SnO<sub>2</sub> based electrodes encounter instability problems in electrochemical energy storage applications. The volume expansion and agglomeration of the SnO<sub>2</sub> particles during the electrochemical cycles lead to discontinuity or cracks in the electrode. This eventually leads to the loss of contact between the electrode materials and the substrate, development of mechanical stresses and reduced charge transfer. The instability of the SnO<sub>2</sub> electrode material can be solved by incorporating the SnO<sub>2</sub> on a suitable supportive material having a large surface area with the ability to hold the SnO<sub>2</sub> on its surface to enable the charge transfer between SnO<sub>2</sub> and electrolyte.*

### **2.4 Review on MoS<sub>2</sub> Nanosheets**

Atomic layer molybdenum disulfide (MoS<sub>2</sub>) comes under the family of two-dimensional materials, like graphene, hexagonal boron nitrate, etc. A MoS<sub>2</sub> sheet has a layer of Mo atoms sandwiched between the layers of S atoms with a strong covalent bond. The adjacent MoS<sub>2</sub> sheets are held together by weak van der Waals forces (Le Mogne 1994). The MoS<sub>2</sub> nanosheets are attractive due to their two-dimensional structure, high surface area (> 210 m<sup>2</sup> g<sup>-1</sup>), tuneable band gap and electronic properties (Wang et al. 2015). The MoS<sub>2</sub> nanosheets are easily coated over various substrates owing to their two-dimensional structure and mechanical flexibility (Ji et al. 2019). Also, the surface of the MoS<sub>2</sub> nanosheets can be functionalised by using zero-dimensional (0D) and one-dimensional (1D) nanomaterials.

### **2.4.1 Optoelectronic properties**

The stable 2H phase of MoS<sub>2</sub> exhibits semiconductor behaviour (Eda et al. 2011). The bulk MoS<sub>2</sub> has an indirect band gap of 1.2 eV. Its band gap value increases with decrease in the crystal thickness because of the quantum confinement effect. The monolayer MoS<sub>2</sub> shows a direct band gap of 1.9 eV (Eda et al. 2011) (Gupta et al. 2020). The MoS<sub>2</sub> nanosheets continue to attract interest in the field of optoelectronics and photocatalysis due to this indirect to direct and small to large band gap tunability.

### **2.4.2 Electronic properties**

The MoS<sub>2</sub> nanosheets are a promising material for next-generation thin film transistor (TFT) applications. The mono/few layers of MoS<sub>2</sub> nanosheets show high carrier mobility of 100 to 200 cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup> and a high on/off current ratio of 10<sup>8</sup> which are the essential characteristics for an active material in a transistor (Gupta et al. 2020). Many works are reported on MoS<sub>2</sub> nanosheets based thin film transistors towards the applications like non-volatile rewritable memory devices (Liu et al. 2012) (Liao et al. 2019) (Liao et al. 2020).

### **2.4.3 Thermal properties**

Li et al. (2014) conducted thermogravimetric analysis (TGA) on MoS<sub>2</sub> and MoS<sub>2</sub>/conductive polymer composite to study the thermal degradation behaviour. It showed that MoS<sub>2</sub> was stable up to 600 °C. Zhou et al. (2014) also reported that MoS<sub>2</sub> is thermally stable up to 700 °C. It was once again confirmed from the reported work by Qin et al. (2014).

### **2.4.4 Mechanical flexibility**

The materials should not fail after repeated bending cycles to use in a flexible device application. They should not lose their properties after a certain period of time. The MoS<sub>2</sub> monolayer sheet shows good mechanical properties due to its strong Mo-S covalent bond (Gupta et al. 2020). Bertolazzi et al. (2011) investigated the mechanical properties of MoS<sub>2</sub> sheets. The monolayer and few-layer MoS<sub>2</sub> sheets were deformed and even broken using an atomic force microscope. The Young's modulus of the

monolayer MoS<sub>2</sub> was found to be  $270 \pm 100$  GPa which is higher than stainless steel. Peng and De (2013) used density functional theory (DFT) to investigate mechanical properties, such as ultimate tensile strain and in-plane stiffness. The estimated value of ultimate tensile strain was 0.24-0.37 and in-plane stiffness was 120 N/m. The reported works concluded that the MoS<sub>2</sub> nanosheets are very flexible and can be used on any kind of substrates.

#### **2.4.5 Electrochemical properties**

The MoS<sub>2</sub> nanosheets are very good candidate materials to be used for energy storage applications due to the characteristics such as high surface area, planar electronic transportation and good stability (Huang et al. 2014). The hydrothermally synthesised MoS<sub>2</sub> nanosheets and MoS<sub>2</sub> microflowers were tested as the electrode materials for the supercapacitor application. The corresponding specific capacity was measured as  $129.2 \text{ F g}^{-1}$  and  $167.7 \text{ F g}^{-1}$  at the current density of  $1 \text{ A g}^{-1}$  (Huang et al. 2014) (Xu et al. 2016). These high specific capacity values of the MoS<sub>2</sub> electrodes were due to their high surface area and layered structure that enhanced the interaction between the electrode and the electrolyte. The MoS<sub>2</sub> based hybrids with materials like graphene and polyaniline reported increased specific capacity (Ren et al. 2019) (Hota et al. 2020).

The MoS<sub>2</sub> is a potential anode material for lithium-ion battery applications because of its layered structure that can allow the lithium ions to intercalate into them. As the weak van der Waals force binds the neighbouring MoS<sub>2</sub> layers, the S-S bonds are broken and Li-S bonds are formed by the intercalated lithium ions (Du et al. 2010). The electrochemical performance of the MoS<sub>2</sub> can be improved by incorporating them into a high conductive network. The MoS<sub>2</sub> nanosheets with a carbon layer improved the conductivity that resulted in a high specific capacity of  $1001 \text{ mAh g}^{-1}$  (Liang et al. 2013). Similarly, different hybrid MoS<sub>2</sub> based anode materials were prepared with various conductive supportive networks such as macro-micro-mesoporous carbon structure (Huang et al. 2019) and 3D porous charcoal network structure (Xu et al. 2019). So, it is clearly understood that the MoS<sub>2</sub> nanosheets are an excellent candidate to be used for electrochemical storage applications.

## **2.4.6 Electrochemical performance of MoS<sub>2</sub> nanosheets hybrid electrodes**

Stability and charge transportation are the essential properties of any material used for electrochemical energy storage applications, such as batteries and supercapacitors. The MoS<sub>2</sub> nanosheets are two-dimensional materials with a large surface area like graphene. There are many reports that show the ability of MoS<sub>2</sub> nanosheets in enhancing the electrochemical performance of metal oxide and conductive polymers based supercapacitors (Zhao et al. 2017) (Alamro and Ram 2017).

Huang et al. (2013) prepared a composite of polyaniline (PANI)/MoS<sub>2</sub> nanosheets for the supercapacitor application. The specific capacitance of PANI was increased by two folds because of added MoS<sub>2</sub> nanosheets. The equivalent series resistance (ESR) of PANI was reduced from 2.05  $\Omega$  to 1.25  $\Omega$  by compositing it with MoS<sub>2</sub>. The reason for this improvement is believed to be the rapid movement of charge carriers back and forth through the MoS<sub>2</sub> nanosheets. Also, MoS<sub>2</sub> nanosheets serve as a high surface area support for PANI, which enhanced the interaction between electrode and electrolyte. It facilitated the rapid transport of electrolyte ions to the electrode during the charge-discharge process. Moreover, the composite lost only 2% of its specific capacitance after 500 cycles.

The poor conductivity of the electrode often reduces the capacity and cyclability of metal oxides such as Co<sub>3</sub>O<sub>4</sub> (Liang et al. 2015) and Mn<sub>3</sub>O<sub>4</sub> (Wang et al. 2016a), MnO<sub>2</sub> (Zhang et al. 2020b) and NiFe<sub>2</sub>O<sub>4</sub> (Zhao et al. 2017). This could be enhanced by incorporating MoS<sub>2</sub> nanosheets with them. The composite of such materials with MoS<sub>2</sub> nanosheets showed the enhanced current values in cyclic voltammetry tests. The discharge time was also increased for such composite materials.

## **2.4.7 Synthesis methods**

### ***2.4.7.1 Chemical vapour deposition***

The molybdenum (Mo) source material and sulfur source material are kept inside a horizontal tube furnace and heated. Because of the heating, the source materials get evaporated. The Ar gas or N<sub>2</sub> gas is purged inside from one end of the tube furnace. The vapours of Mo and sulfur are carried by this gas and get condensed onto the

substrate. A single layer of MoS<sub>2</sub> film is produced from this process. This method is called as chemical vapour deposition (CVD).

Lee et al. (2012b) and Tsai et al. (2014) produced the few layers MoS<sub>2</sub> with MoO<sub>3</sub> and sulfur as source materials. The CVD process was carried out in a tube furnace, kept at 650 °C, under N<sub>2</sub> gas flow. Heating for 15 minutes produced atomic layers of MoS<sub>2</sub> films. Yu et al. (2013a) used MoCl<sub>5</sub> powder as Mo source. High quality MoS<sub>2</sub> film was deposited with 10 minutes of heating at 850 °C under Ar gas flow.

#### ***2.4.7.2 Mechanical methods***

Mechanical exfoliation is another technique to produce high-quality layers of MoS<sub>2</sub> sheets. This technique was used to exfoliate graphene from graphite flakes (Novoselov et al. 2004). In this method, each layer of graphite was peeled off by scotch tape till its thickness was reduced to few graphite layers. This technique was adapted to produce MoS<sub>2</sub> nanosheets. Bertolazzi et al. (2011) exfoliated MoS<sub>2</sub> sheets from the bulk molybdenite. The obtained nanosheets were dissolved and captured on PVA and PMMA coated SiO<sub>2</sub> substrate. Then PVA and PMMA layer were released by dissolving them in water and vacuum heating at 400 °C for 4 hours. In the end, MoS<sub>2</sub> was transferred to SiO<sub>2</sub> substrate. Choi et al. (2012) and Kwon et al. (2015) also used the mechanical exfoliation method to obtain MoS<sub>2</sub> film to fabricate MoS<sub>2</sub> film based transistor.

#### ***2.4.7.3 Physical vapour deposition***

Le Mogne (1994) prepared MoS<sub>2</sub> films for super-lubrication application. The MoS<sub>2</sub> sputtering target was made from the MoS<sub>2</sub> powder. The films on different substrates were prepared by sputter depositing MoS<sub>2</sub> by using radio-frequency (RF) magnetron sputtering system.

Ma and Shi (2013) placed MoS<sub>2</sub> pellets in a cubic iron box with small pinholes. Then, this box and Si substrate were kept inside a horizontal tube furnace. The furnace was heated to 500 °C and Ar gas was supplied into the furnace at a rate of 10~30 sccm. The MoS<sub>2</sub> got evaporated and came out through the pinholes to form a narrow vapour beam.

The reaction time was varied between 2-10 minutes to produce MoS<sub>2</sub> film on the Si substrate.

Though CVD, PVD and mechanical exfoliation method produces high-quality MoS<sub>2</sub> sheets, it has limitations, namely, the need for high temperature heating, transfer of film onto another substrate and low yield.

#### ***2.4.7.4 Lithium intercalation method***

The bulk MoS<sub>2</sub> powder was soaked in a lithium based solvent. After allowing sufficient time for lithium to intercalate into the MoS<sub>2</sub> layers, the solution was mixed with water and ultrasonicated. Also, it was assumed that when water and intercalated Li interact, hydrogen gas is produced. The MoS<sub>2</sub> layers are separated as the hydrogen gas expands.

Joensen et al. (1986) exfoliated single-layer MoS<sub>2</sub> from the bulk MoS<sub>2</sub> powder using 1.6 M n-butyl lithium in hexane under Ar gas atmosphere. Eda et al. (2011) heat-treated the MoS<sub>2</sub> sheets which were produced from Li intercalation technique. They annealed the MoS<sub>2</sub> sheets at 300 °C in the Ar atmosphere. This treatment restored 2H semi conductive phase from the bulk powder that is needed for transistor application. Voiry et al. (2013) and Acerce et al. (2015) synthesised 1T phase MoS<sub>2</sub> by Li intercalation method for hydrogen evolution.

Dungey et al. (1998) explained the structural change involved in MoS<sub>2</sub> bulk sheets during Li intercalation. In bulk MoS<sub>2</sub> (2H phase), the sulfur atoms are in a hexagonal close-packed arrangement. The Mo atoms are sandwiched between the S atoms so that Mo will have six coordinated S atoms to form trigonal prismatic geometry. The van der Waals force holds the sandwiched layers together. During the intercalation, Li donates one electron to the d-band of MoS<sub>2</sub> and Li<sup>+</sup> goes and sits between two sandwiched layers.

Figure 2.5 Top and side views of the a) 2H and b) 1T arrangement of MoS<sub>2</sub> (Gupta et al. 2020)

The MoS<sub>2</sub> layers get reduced and transform into 1T phase with octahedrally coordinated Mo atoms. The 2H phase exhibits a semiconductor nature whereas the 1T phase exhibits metallic nature. This 1T phase exists along with the 2H phase in the Li intercalated MoS<sub>2</sub> sheets.

In this process, there is a necessity to take precautionary measures during the handling of n-butyl lithium. This reacts violently with the water and needs to be stored under the inert gas atmosphere to prevent activity loss.

#### 2.4.7.5 Solvent aid or liquid exfoliation

Coleman et al. (2011) separated individual MoS<sub>2</sub> sheets with the assistance of organic solvent, N- methyl-pyrrolidone (NMP). The bulk MoS<sub>2</sub> powder was dispersed in the solvent. This dispersion was ultrasonicated to exfoliate the MoS<sub>2</sub> nanosheets. Then the resultant dispersion was centrifuged and the supernatant was collected. This final supernatant dispersion contained mixed mono-, bi-layer and few layer MoS<sub>2</sub> sheets.

Anbazhagan et al. (2014) used thioglycolic acid to exfoliate MoS<sub>2</sub> sheets from the bulk MoS<sub>2</sub> powder. Li et al. (2014) reported MoS<sub>2</sub> exfoliation using 45% ethanol-water mixture as the solvent. Narayanan et al. (2014) used dimethylformamide (DMF) as the solvent. Mishra et al. (2015) used a mixture of DM water and soap detergent as the

solvent. Weng et al. (2015) used NMP as the solvent to exfoliate the bulk MoS<sub>2</sub> powder into mono or few layer thick MoS<sub>2</sub> sheets.

#### ***2.4.7.6 Hydrothermal method***

Huang et al. (2014a) synthesised MoS<sub>2</sub> nanosheets with sodium molybdate as the molybdenum source and L-cysteine as the sulfur source. The source materials were dissolved in DM water and ultrasonicated. Then it was transferred to a Teflon-lined autoclave. The autoclave was subjected to heat at 180 °C for 48 hours. The product was washed several times with water and ethanol, then vacuum dried at 80 °C for 12 hours.

Ren et al. (2015) used dibenzyl disulfide as the sulfur source instead of L-cysteine to synthesis MoS<sub>2</sub> nanosheets. The mixture of sodium molybdate in water and dibenzyl disulfide in ethanol was ultrasonicated. Then the mixture was transferred to a Teflon-lined autoclave and heated at 220 °C for 18 hours. The resultant suspension was centrifuged and the supernatant containing the MoS<sub>2</sub> sheets were collected.

#### **Critical review on MoS<sub>2</sub> nanosheets**

*The liquid phase exfoliation of MoS<sub>2</sub> nanosheets is a simple and high yield route. The MoS<sub>2</sub> nanosheets have high mechanical strength and flexibility and excellent electrochemical stability. They are ideal materials to be used for energy storage applications like supercapacitors and batteries. It is reported that the electrochemical performance of the supercapacitors based on metal oxides like SnO<sub>2</sub>, Mn<sub>2</sub>O<sub>3</sub> and Co<sub>3</sub>O<sub>4</sub> can be enhanced by composite them with the MoS<sub>2</sub> nanosheets.*

#### **2.5 Objectives of the Study**

Silver nanowires could be synthesised with the presence of an alternative oxygen scavenger, other than Cu/Fe, to improve the aspect ratio of the silver nanowires. The manganese (Mn) ions have not been explored as the oxygen scavenger till now. The characteristics of manganese, such as (i) tendency to remove more oxygen owing to its high negative free energy for oxidation; (ii) large number of oxidation states (2, +3, +4, +5, +6 and +7) compared to that of Cu (+1 and +2) and Fe (+2 and +3) are expected to help in removing the oxygen effectively from the surface of silver seed particles.

The high solubility of the Zn/ZnO anode in the alkaline electrolyte could be controlled by changing the morphology into one-dimensional rod-like structures from the conventional cubic, prism-like structure. The hydrogen gas evolution and corrosion problems could be minimized by adding SnO<sub>2</sub> nanoparticles and two-dimensional MoS<sub>2</sub> nanosheets as additives to the anode material. The SnO<sub>2</sub> is an effective additive to Zn/ZnO anode in suppressing the hydrogen gas evolution and enhancing the conductivity. The MoS<sub>2</sub> nanosheets offer a large specific surface area similar to graphene. They can improve the interaction between the electrode and the electrolyte and facilitate charge transfer. The MoS<sub>2</sub> nanosheets can act as the conductive bridge between the individual ZnO and SnO<sub>2</sub> particles. The use of both MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles together as an additive to Zn/ZnO anode is rarely explored. The composite of MoS<sub>2</sub>-SnO<sub>2</sub> as an additive would bring the benefits from these materials for the betterment of zinc-based anode in alkaline batteries.

Hence, the following objectives are formulated.

- 1. Fabrication of transparent conductive film of the silver nanowires synthesised in the presence of different chloride salts**
  - Synthesis and characterization of the silver nanowires with the presence of NaCl, CuCl<sub>2</sub> and MnCl<sub>2</sub>
  - Preparation and characterization of the transparent conductive Ag NWs film made using spray coating
  - Testing of silver nanowires film for transparent heater application
- 2. Synthesis and characterization of MoS<sub>2</sub> nanosheets**
  - Analysing the nature and purity of the synthesised MoS<sub>2</sub> nanosheets
- 3. Preparation of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite for supercapacitor applications**
  - Preparation of nanocomposite of MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles and its electrochemical characterization for supercapacitor application
- 4. Preparation of hybrid MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO anode for zinc alkaline battery application**
  - Synthesis of ZnO microrods, nanorods and their electrochemical characterization in the alkaline electrolyte (KOH)

- Electrochemical characterization of the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO hybrid electrode in the alkaline electrolyte (KOH)

## **2.6 Scope of the study**

The study will help to understand the importance of oxygen scavengers during the synthesis of silver nanowires used to fabricate the flexible transparent conductive silver nanowires films. The study will help to realize the significance of appropriate additives and morphology of the electrode material in enhancing their electrochemical performance for the energy storage applications such as supercapacitors and alkaline batteries.

## CHAPTER 3

### MATERIALS AND METHODOLOGY

*This chapter presents the details on the materials preparation and their various characterizations. The present chapter has three sections. They are 1. Fabrication of flexible transparent conductive silver nanowire films and their characterizations; 2. Preparation of  $\text{MoS}_2\text{-SnO}_2$  nanocomposite and its characterizations; 3. Preparation of ZnO hybrid electrodes and their electrochemical characterizations.*

#### 3.1 Flexible Transparent Conductive Silver Nanowires Film

The fabrication of flexible transparent conductive silver nanowires films involves the synthesis of silver nanowires, purification process to separate the nanowires from by-products, coating silver nanowires on the desired substrate and post-film treatment to improve its properties.

##### 3.1.1 Synthesis of silver nanowires

The silver nanowires were synthesised by the polyol method (Coskun et al. 2011). The materials used for the synthesis process are silver nitrate (SRL Laboratories, 99.9%), polyvinylpyrrolidone (Molychem), NaCl (TCI chemicals, >99.5%),  $\text{CuCl}_2 \cdot 5\text{H}_2\text{O}$  (SRL Laboratories, 98%),  $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$  (Nice chemicals, 95%) and ethylene glycol (Nice chemicals, 99%). The concentrations of the chemicals were optimized as follows.

First, the solutions of silver nitrate ( $\text{AgNO}_3$ ), polyvinylpyrrolidone (PVP, M.W.=40,000), NaCl (44.5 mM),  $\text{CuCl}_2 \cdot 5\text{H}_2\text{O}$  (22 mM) and  $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$  (22 mM, 40 mM and 65 mM) were prepared by using ethylene glycol (EG) as solvent. A flask containing 15 ml solution of 0.147 M PVP was heated for 45 minutes at 170 °C in an oil bath under magnetic stirring. Then, 75  $\mu\text{L}$  of chloride solution (NaCl or  $\text{CuCl}_2 \cdot 5\text{H}_2\text{O}$  or  $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ ) was added to the flask. After three minutes, 3 ml  $\text{AgNO}_3$  (0.153 M) solution was added to the flask. Upon adding  $\text{AgNO}_3$ , the solution was continued to be heated for another 2 hours for the growth of nanowires. After 2 hours of heating, the solution was removed from the oil bath and allowed to cool in the air. Finally, the as-synthesised product was washed with acetone and isopropyl alcohol.

### 3.1.2 Purification of silver nanowires

Two methods were explored to separate the silver nanowires and the particles produced from the synthesis step as by-products. Conventional centrifugation was the first method employed to remove undesirable silver particles (Jarrett and Crook 2016).

Figure 3.1 Purification of Ag nanowires by centrifugation process

In this method, as shown in Fig. 3.1, the silver product synthesised with the presence of Cu(II) ions was mixed with acetone and centrifuged at 4000 rpm for 20 minutes. After the completion of centrifugation, the supernatant was removed. Then, the isopropyl alcohol (IPA) was added to the precipitation settled at the bottom of the centrifuge tube. Now, the dispersion in IPA was centrifuged at 3000 rpm for 20 minutes. The supernatant in the tube was removed again. This step was repeated two more times. At last, the product settled at the tube bottom was dispersed in IPA and kept for storing.

The second method was the decantation and solvent-aid purification process. The as-synthesised silver product, synthesised with the presence of Cu(II) ions (and Mn(II) ions), was kept for settling for 12 hours. The product which remained as the supernatant was removed out from the flask (decantation). Next, acetone was added to the flask. The mixture was ultrasonicated for 2 minutes. This led the mixture to coagulate and settle at the bottom. The remained supernatant at this stage was removed. Now, the IPA solvent was added into the settled precipitation. The added IPA dispersed the precipitate. Next, the dispersed products were allowed to settle down slowly. After 15 minutes of time, the top half of the dispersion was removed, leaving the half-settled product in the flask itself. Both the supernatant and settled products at this stage were used for further characterization. Various stages involved in this purification method are schematically presented in Fig. 3.2.

Figure 3.2 Schematic representation of the decantation and solvent-aid purification process

### 3.1.3 Coating transparent conductive silver nanowires film

Figure 3.3 Spray coating of silver nanowires films

The silver nanowires films were prepared by spray coating technique. The silver nanowires dispersed in IPA were loaded into a commercial airbrush kit and spray-coated on the glass or plastic film substrate kept on a hot plate at 80 °C. The air pressure

used was 68.9 kPa (10 psi). The distance between the spray gun and the substrate was 15 cm. Later, the prepared silver nanowires films were subjected to annealing at 165 °C for 30 minutes to reduce the sheet resistance.

### **3.1.4 Characterization of silver nanowires and film**

The prepared silver nanowires and silver nanowires films were subjected to various characterizations to analyse the growth, morphology, dimensions (length and diameter), stability under mechanical bending movements, electrical and optical properties which are essential to be used for transparent conductive applications (Langley et al. 2013).

#### ***3.1.4.1 X-ray diffractometry***

The structural characterizations, such as phase identification and crystal growth direction of the synthesised silver nanowires were performed by using X-ray diffractometer (XRD; JDX 8P, JEOL) with Cu K $\alpha$  ( $\lambda=0.154$  nm) radiation. The XRD pattern was obtained in the  $2\theta$  range from 30° to 70° at the scan rate of 2°/min and step size of 0.02°. The sample was prepared by drop-casting the purified silver nanowires dispersed in IPA on a glass substrate. The collected XRD data was analysed by comparing it with the standard ICDD files.

#### ***3.1.4.2 Scanning electron microscopy***

The morphological studies of the synthesised materials were carried by using scanning electron microscope (SEM) (JSM-6380LA, JEOL) and field emission scanning electron microscopy (FESEM; Carl Zeiss Sigma). The dimensions of the synthesised products were measured from the SEM/FESEM micrographs by using ImageJ software.

#### ***3.1.4.3 Transmission electron microscopy***

The detailed morphological analysis of synthesised materials and selected-area electron diffraction (SAED) were obtained by using transmission electron microscope (TEM) (JEM-2100, JEOL). The samples for TEM analysis were prepared by diluting the synthesised materials with IPA and ultrasonicate them for 10 minutes. This step was essential to avoid the agglomeration of the synthesised materials. Then, one or two drops were taken from the middle of the dispersion and drop-casted on the 3 mm

diameter carbon-coated copper grid. The samples deposited on the copper grid were dried in order to remove the moisture from the samples.

#### ***3.1.4.4 UV-VIS spectroscopy***

The optical absorption and transmittance spectra of the synthesised silver nanoparticles, silver nanowires and silver nanowires films were obtained by using UV-VIS spectrometer (SD2000, Ocean Optics). All the samples were dispersed in isopropyl alcohol solvent for the absorption spectra measurement. Isopropyl alcohol was used as the reference liquid for this measurement.

#### ***3.1.4.5 Electrical resistance test***

The sheet resistance ( $R_s$ ) of the coated silver nanowires films was measured by using four-probe measurement setup (SES instruments, India). The change in sheet resistance of the film subjected to the mechanical flexibility test was measured by the two-probe method using Fluke 15b+ multimeter. The silver paste was used to make electrical contacts at the two ends of the films for this purpose. A silver nanowires film of 2.5x2.5 cm coated on the plastic substrate was used as the sample. The width of the silver contacts was 3 mm.

#### ***3.1.4.6 Mechanical flexibility test***

The silver nanowires film was spray-coated on a flexible plastic film to test the mechanical flexibility of the synthesised silver nanowires. The prepared film was bent to a curvature of 4.5 mm radius for 500 bending cycles. An ITO coated PET film was also subjected to this bending test for comparison purpose. The change in sheet resistance of silver nanowires film and ITO/PET was measured after every ten bending cycles.

Figure 3.4 Bending test to examine the mechanical flexibility of the film

#### 3.1.4.7 Transparent heater test

Electrical contacts were made at the two ends of the silver nanowires film by using the silver paste. The setup to test the heater performance of the silver nanowires film is shown in Fig. 3.5.

Figure 3.5 Silver nanowires film heater testing setup

The heater test was performed by applying the electrical potential between two electrical contacts made on the silver nanowires film using Keithley 2400 source meter. The heater test was conducted with different the applied voltages: 5, 7 and 10 V. The

temperature generated on the film in response to the applied potential was measured by using an infrared thermometer (HT-826; Temp. resolution= 0.1 °C).

### 3.2 MoS<sub>2</sub>-SnO<sub>2</sub> Nanocomposite for Energy Storage Applications

The MoS<sub>2</sub> nanosheets are an excellent additive material to improve the performance of the metal oxides for electrochemical energy storage applications such as supercapacitors and batteries (Wang et al. 2016a) (Pan et al. 2016). The present work demonstrates the enhancement of electrochemical performance and stability of the SnO<sub>2</sub> nanoparticles by functionalizing them on the MoS<sub>2</sub> nanosheets.

#### 3.2.1 Synthesis of MoS<sub>2</sub> nanosheets

The MoS<sub>2</sub> nanosheets were prepared by the ultrasonication-assisted liquid-phase exfoliation method (Liu et al. 2012). First, 150 mg of polyvinylpyrrolidone (PVP, MW~40,000) was dissolved in 10 ml ethanol. Next, 30 mg of bulk MoS<sub>2</sub> powder (Alfa Aesar, 325 mesh) was added to the above-prepared PVP solution. The mixture of MoS<sub>2</sub> and PVP in ethanol was ultrasonicated (Power= 50 W, f=33 kHz) for 4 hours to exfoliate the MoS<sub>2</sub> nanosheets.

Figure 3.6 Exfoliation of MoS<sub>2</sub> nanosheets

After the exfoliation process, the exfoliated MoS<sub>2</sub> sheets which remained on top of the solution were transferred to the centrifugal tubes for washing. The product was mixed with acetone and centrifuged at 7000 rpm for 20 minutes. After removing the supernatant, isopropyl alcohol (IPA) was added to the precipitation settled at the bottom of the centrifugal tube. This exfoliated MoS<sub>2</sub> dispersion was again centrifuged at 8000 rpm for 20 minutes. Finally, the washed product was collected and suspended in IPA for storing.

### **3.2.2 Synthesis of SnO<sub>2</sub> nanoparticles**

The SnO<sub>2</sub> nanoparticles were synthesised by following the work reported in the literature (Bob et al. 2016). First, 1 g of tin chloride pentahydrate (SnCl<sub>4</sub>.5H<sub>2</sub>O) was dissolved in 10 ml of ethylene glycol (EG). It was followed by the addition of 250 mg of ammonium chloride, 250 mg of ammonium acetate and 30 ml de-mineralized (DM) water in a round bottom flask. Then, the flask was heated to 90 °C in the oil bath for 2 hours. Upon heating, the synthesised product was washed with DM water and ethanol. Finally, the washed SnO<sub>2</sub> nanoparticles were dispersed in ethanol.

### **3.2.3 Functionalization of MoS<sub>2</sub> nanosheets with SnO<sub>2</sub> nanoparticles**

The known density of MoS<sub>2</sub> nanosheets dispersion was added into a vial containing the known weight of SnO<sub>2</sub> nanoparticles dispersion. Then the two materials were well dispersed together by using ultrasonication bath. After the ultrasonication, the materials were allowed to get settled at the bottom of the vial. Then the supernatant liquid was removed and the materials settled at the bottom were used for our study. Likewise, five different compositions of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposites were prepared with varying the weight ratio of MoS<sub>2</sub> nanosheets (0.5%, 1%, 2.5%, 5% and 10%) to SnO<sub>2</sub> nanoparticles. The camera images of each step involved in this preparation process are shown in Fig. 3.7.

Figure 3.7 Camera images show the steps involved in the preparation of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

### 3.2.4 Characterization of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

#### 3.2.4.1 X-ray diffractometry

The structural characterization and phase identification of the synthesised materials were performed by using X-ray diffractometer (XRD; JEOL, JDX 8) with Cu K $\alpha$  ( $\lambda=0.154$  nm) radiation at the scan rate of 1°/min and step size of 0.02°. The XRD patterns were collected in the  $2\theta$  range from 10° to 60°. The MoS<sub>2</sub> nanosheets, SnO<sub>2</sub> nanoparticles and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite were drop-casted on the glass substrate and used as the samples. The collected XRD data were analysed by comparing it with the standard ICDD files.

#### ***3.2.4.2 Scanning electron microscopy***

The morphological studies of the synthesised materials were carried by using field emission scanning electron microscopy (FESEM; Carl Zeiss Sigma). The sample preparation for FESEM analysis was done by drop casting the dispersion of MoS<sub>2</sub> nanosheets and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite on a glass slide. Upon drying, the samples deposited on the glass slide were sputter-coated with thin gold layer before used for the FESEM analysis.

#### ***3.2.4.3 Transmission electron microscopy***

The detailed morphology of the synthesised materials and selected-area electron diffraction (SAED) were analysed by using transmission electron microscope (TEM) (JEM-2100, JEOL make). The samples were drop cast on a 3 mm diameter carbon-coated copper grid.

#### ***3.2.4.4 Raman spectroscopy***

The Raman spectra of bulk and exfoliated MoS<sub>2</sub> were obtained by using Raman spectrometer (Horiba Jobin-Yvon, labRAM HR) with an excitation wavelength of 532 nm.

#### ***3.2.4.5 X-ray photoelectron spectroscopy***

The X-ray photoelectron spectrometer (XPS) was performed to analyse the nature of materials by determining their present oxidation states from their binding energy peaks. The surface chemistry of the materials was analysed by using X-ray photoelectron spectrometer (XPS; Thermo scientific, Multilab 2000) instrument (Mg K $\alpha$  X-ray, 200 W excitation source).

#### ***3.2.4.6 Particle size analysis***

The particle size of SnO<sub>2</sub> nanoparticles was determined by using particle size analyser (Malvern Zeta Sizer, NanoZS). The particle size distribution obtained from this study was used to compare it to the average particle size measured from the electron microscopic study.

#### **3.2.4.7 Surface area analysis**

The specific surface area and pore size distribution of MoS<sub>2</sub> nanosheets were analysed by Brunauer–Emmett–Teller (BET) and Barrett–Joyner–Halenda (BJH) method using surface area analyser (Microtrac, BELSORP Max). It was necessary to measure the specific surface area of the MoS<sub>2</sub> nanosheets as the charge transfers during the electrochemical cycles are facilitated through the surface of MoS<sub>2</sub> nanosheets.

#### **3.2.4.8 Electrochemical characterization**

Electrochemical studies were carried out with a standard three-electrode cell using SP-150 electrochemical workstation (BioLogic, France). Platinum wire and saturated calomel electrode (SCE) were used as the counter electrode and reference electrode, respectively. The working electrode was prepared as follows: 4.5 mg of nanocomposite was added into 250 µL water/ethanol (2:1 v/v) solution containing 15 µL Nafion (5 wt%). The above mixture was ultrasonicated for 15 minutes to obtain a homogeneous mixture. 50 µL of the prepared mixture was drop cast on a graphite electrode (10 mm diameter rod). The calculated mass of the active electrode material was 1.1 mg cm<sup>-2</sup>. The aqueous solution of 2 M KOH dissolved in DM water was used as the electrolyte.

### **3.3 Electrochemical Performance of ZnO Hybrid Electrode in Alkaline Electrolyte**

The ZnO is used as the anode material in zinc batteries that use alkaline electrolytes. The performance, life cycle and rechargeability of these batteries depend on the stability of the anode. Morphological changes, solubility in the electrolyte and H<sub>2</sub> gas evolution at the anode are the important factors to be considered to achieve a good battery performance (Zhang et al. 2018b). The present work deals with the mentioned factors by engineering the morphology of the anode material and additives added to the anode material.

#### **3.3.1 Synthesis of one dimensional ZnO rods**

The concentrations of the precursors used were optimized to the laboratory condition. ZnO nanorods were synthesised by microwave heating. 22 g of Zn(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O and 4.2 g of KOH were dissolved in 100 ml de-mineralized (DM) water. Then, ammonia was

added into this solution dropwise under continuous stirring to bring the pH value to 11. After that, the prepared solution was heated in a microwave oven at 700 W for 5 min. The final product was then washed with the DM water and the ethanol for three cycles.

ZnO microrods were synthesised by the hydrothermal method. 4.5 g of  $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and 0.850 g of KOH were dissolved in 30 ml de-mineralized (DM) water. Ammonia was added into the solution dropwise under continuous stirring to adjust the pH value to 11. Then, the entire solution was transferred to a Teflon-lined stainless autoclave. This autoclave was heated in a hot air oven at 180 °C for 48 h. Finally, the final product was washed with the DM water and the ethanol for three cycles. Commercial ZnO nanoparticles (Platonic Nanotech, India) were used in this study to compare the performance of synthesised ZnO samples.

### **3.3.2 MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO preparation**

The preparation of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite is explained earlier in section 3.2.3. The 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite powder was added as the additives to the ZnO powders (ZnO nanoparticles, ZnO nanorods and ZnO microrods). The mixtures were then added into the PVA dissolved in DM water. The PVA was serving as the binder. The weight ratio of ZnO, MoS<sub>2</sub>-SnO<sub>2</sub> and PVA was maintained at 75:15:10, respectively.

### **3.3.3 Material characterization of ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO:**

The structural characterization of synthesised ZnO rods and commercial ZnO nanoparticles was performed by using X-ray diffractometer (XRD; JEOL, JDX 8) with Cu K $\alpha$  ( $\lambda=0.154$  nm) radiation at the scan rate of 1°/min and step size of 0.02°. The collected XRD data was analysed by comparing it with the standard ICDD files. The morphological studies of the ZnO materials were carried by using field emission scanning electron microscopy (FESEM; GeminiSEM 500, Carl Zeiss).

### **3.3.4 Material solubility test**

The solubility of ZnO materials in the alkaline electrolyte was determined. 5 mg of ZnO nanorods, ZnO microrods and commercial nanoparticles, each were added into separate vials that contained 6 M KOH in water solution. After 12 hours, the supernatant solution

was taken out from each ZnO sample vial and subjected to atomic absorption spectroscopy (AAS) analysis. The analysis was performed by using GBC 932 atomic absorption spectrometer.

### 3.3.5 Electrochemical measurements

The electrochemical studies of all ZnO materials were performed with the three-electrode cell setup by using Flex-OGF05A potentiostat (Origaly's, France) and OrigaFlex-OGFEIS impedance analyser (Origaly's, France). The ZnO powder (ZnO nanoparticles, ZnO nanorods and ZnO microrods) was added into the binder solution of PVA dissolved in DM water. The well-mixed slurry of ZnO was drop-casted on the glassy carbon electrode. This was used as the working electrode for electrochemical studies. The platinum wire and saturated calomel electrode were used as counter electrode and reference electrode, respectively. The 6 M KOH dissolved in water was used as the electrolyte (Yang et al. 2018).

- i. Prior to all the electrochemical tests, the electrochemical cell was in open-circuit potential for 10 minutes to ensure that the cell reached a steady state.
- ii. The cyclic voltammetry (CV) test was conducted in the potential range from -2 V to -0.95 V at the scan rate of  $10 \text{ mV s}^{-1}$  as the anodic and cathodic peaks of ZnO are expected to be appeared in this range (Renuka et al. 2001).
- iii. Potentiodynamic polarization was used to study the corrosion behaviour of ZnO materials. The test was performed at the scan rate of  $1 \text{ mV s}^{-1}$ . The potential range was selected so that ' $E_{\text{corr}}$ ' of ZnO in KOH electrolyte fall in this range (Huang et al. 2014a). The Tafel curve was obtained by plotting the values of potential versus  $\log I$  (current).
- iv. Linear sweep voltammetry (LSV) was performed at the potential range from 0 V to -2.5 V at the scan rate of  $5 \text{ mV s}^{-1}$ . The wide range of potential was selected to observe the current response to study the hydrogen gas evolution in the material.
- v. Electrochemical impedance spectroscopy (EIS) was carried out with the AC sine wave amplitude of 10 mV in the frequency range from 0.1 Hz to 100 kHz.

## CHAPTER 4

### TRANSPARENT CONDUCTIVE SILVER NANOWIRES FILM

*This chapter presents the polyol synthesis of silver nanowires, fabrication of transparent conductive silver nanowires films and its performance as the transparent heater. This chapter discusses the effect of  $MnCl_2$  addition on the morphology of synthesised silver nanowires. The opto-electrical characteristics of fabricated silver nanowires films are discussed in detail.*

#### 4.1 Synthesis and Purification of Silver Nanowires

The SEM micrograph of silver nanowires synthesised with the addition of  $CuCl_2 \cdot 5H_2O$  after the centrifugation process is shown in Fig. 4.1. It is observed that there are still many nanoparticles and microrods present along with the nanowires. In order to use these silver nanowires for transparent conductive electrode (TCE) application, these particles have to be removed. Thus, it was convinced that the centrifugation process alone was not enough to separate silver nanowires (Ag NWs) from the undesired silver particles.

Figure 4.1 SEM micrograph of the synthesised silver product after the centrifugation process

The proposed alternative method, ‘decantation and solvent-aid purification process’ shown in Fig. 3.2, is explained in the following steps. The as-synthesised solution was kept undisturbed overnight for the synthesised products to settle down at the bottom of the flask. This leaves the excess ethylene glycol (EG) and polyvinylpyrrolidone (PVP) along with the small nanoparticles in the supernatant. After removing the supernatant from the flask, the precipitate (sediment) at the bottom of the flask contained only nanowires, nanoparticles and micrometer length rods (Fig. 3.2; Stage 3). In the next step, acetone was added to the precipitate in the flask and ultrasonicated for two minutes. The surface of the silver products (nanowires, particles, rods) was covered by the capping agent, PVP. But the PVP is insoluble in acetone. So, the synthesised nanowires were allowed to settle down like precipitates at the bottom of the flask when acetone was added to it (Fig. 3.2; Stage 4). Due to the lower weight, the nanoparticles were still in the supernatant. When the supernatant was removed between stages 3 and 4, these nanoparticles were separated out from the solution. This was confirmed from the SEM micrograph of the supernatant shown in Fig. 4.2

Figure 4.2 SEM micrograph of supernatant: after the addition of acetone (between stages 3-4, of purification process explained in Fig. 3.2)

Then, isopropyl alcohol (IPA) was added to this precipitate (containing nanowires, rods and large particles) and mixed properly. The PVP molecules are soluble in IPA. So, the precipitates at this stage got dispersed entirely in the IPA solvent. With a holding period, the metallic silver got settled down due to its mass. For the same reason, the

silver nanowires got settled faster than the silver particles. After 15 minutes, the top half of the dispersion was removed, leaving the bottom half in the flask. The top half solution was analysed by SEM and the corresponding micrograph is shown in Fig. 4.3.

Figure 4.3 SEM micrograph of supernatant: after the addition of IPA (between stages 6-7, of purification process explained in Fig. 3.2)

It was observed that the supernatant removed after the addition of IPA (between stages 6-7) contained particles in the size of nanometers and micrometers. Few short rods were also present.

Figure 4.4 a), b) SEM micrographs of silver nanowires after decantation and solvent-aid purification

The bottom half dispersion at the last stage was analysed by SEM and shown in Fig. 4.4. The final product contained nanowires of length 5-20  $\mu\text{m}$ , few particles and short nanowires. By comparing the centrifugation method and the ‘decantation & solvent-aid purification’ method, the second method was more effective in the purification of silver nanowires from the undesired particles. This method was followed for the purification of silver nanowires synthesised with other chloride conditions as well. The yield of silver nanowires was estimated as 72% while the undesired silver nanostructures was 28%.

#### **4.2 Effect of Chloride Salts on the Growth of Silver Nanowires**

The change in the morphology of the synthesised silver products with respect to four different types of chloride solutions is given with the help of FESEM micrographs. The four chloride conditions are, i) without any chloride salt; ii) with the addition of NaCl; iii) with the addition of  $\text{CuCl}_2$  and iv) with the addition of  $\text{MnCl}_2$ .

Figure 4.5 shows the FESEM micrographs of silver products synthesised without any chloride salt. The product synthesised without the addition of any chloride lead to the growth of silver spherical-like particles. The size of the particles was measured to be in the range of 110 nm to 1  $\mu\text{m}$ , with an average size of 330 nm. The dimensions of the silver nanowires were measured with the help of ImageJ software.

Figure 4.5 FESEM micrograph of the silver particles synthesised without the addition of any chloride salt

The rapid reduction of  $\text{Ag}^+$  ions from  $\text{AgNO}_3$  to  $\text{Ag}^0$  during the synthesis process was the reason behind the formation of the silver particles. The reduction reaction of  $\text{Ag}^+$  ions to  $\text{Ag}^0$  is so fast that the reduced silver cannot grow as multi-twin particles. The absence of twins which serve as seeds for nanowires, resulted in the growth of silver particles instead of nanowires. These silver particles subsequently grew into larger particles via Oswald ripening process (Coskun et al. 2011).

Figure 4.6 FESEM micrograph of the silver products synthesised with the addition of NaCl

Figure 4.6 shows the FESEM micrograph of silver product synthesised with the addition of NaCl during the synthesis process. The micrograph shown in Fig. 4.6 reveals that the addition of NaCl promoted the one-dimensional growth of silver that resulted in silver nanorods. It is observed that there are other structures, such as cubes (avg. size= 74 nm) and pyramid (avg. size= 119 nm) particles also produced along with the nanorods. The addition of NaCl prevented the rapid reduction of  $\text{Ag}^+$  ions to  $\text{Ag}^0$  by the formation of AgCl. The AgCl acted as a buffer phase. It ensured the controlled release of silver into the reaction for the one-dimensional growth (Coskun et al. 2011). Hence, the presence of  $\text{Cl}^-$  ions during the synthesis process is important to prevent the formation of silver particles and to promote the one-dimensional growth of silver nanostructures.

Figure 4.7 a), b) Length and diameter distribution of Ag nanorods synthesised with the addition of NaCl

The mean length and diameter of the silver nanorods are 1  $\mu\text{m}$  and 48 nm, respectively (Fig. 4.7). These silver nanowires are very short in length to be used for the TCE application. The film fabricated from these silver nanorods would have more sheet resistance and less optical transparency. The growth of short silver nanorods was the result of oxygen etching of silver twinned particles. During the synthesis, the atomic oxygen ( $\text{O}_a$ ) present in the reaction solution tends to etch away the twinned particles that otherwise serve as the seeds for silver nanowires growth. The etching of twinned seed particles leads to short nanowires or nanorods (Wiley et al. 2004).

Figure 4.8 FESEM micrograph of the silver nanowires synthesised with the addition of  $\text{CuCl}_2$

Figure 4.9 a), b) Length and diameter distribution of silver nanowires synthesised with the addition of  $\text{CuCl}_2$

Figure 4.8 shows the FESEM micrograph of silver nanowires synthesised with the addition of  $\text{CuCl}_2 \cdot 5\text{H}_2\text{O}$  during the synthesis process. The synthesis of silver nanowires with the addition of  $\text{CuCl}_2$  produced nanowires along with a few short rods and particles. The addition of copper chloride in place of  $\text{NaCl}$  is a proven approach to act against the oxygen etching of twinned particles. The mean length of these silver nanowires was enhanced up to 7.2  $\mu\text{m}$  with the maximum length up to 20  $\mu\text{m}$  (Fig. 4.9a) when  $\text{NaCl}$  is replaced with the copper chloride. The introduction of copper ions into the reaction through copper chloride avoided the aggregation of the silver particles.

In addition to that, the copper ions prevented the oxygen etching of twins by scavenging the atomic oxygen from the surface of the twinned silver particles (Korte et al. 2008). But there is a concern with the diameter of the nanowires. The average diameter of the nanowires synthesised with the addition of copper ions was measured as 151 nm (Fig. 4.9b). Although the addition of copper ions helped to enhance the length of the silver nanowires, it also increases the diameter of the nanowires as well. The production of large diameter (125 to 250 nm) silver nanowires synthesised with copper ions is already reported (Bob et al. 2016).

The large diameter silver nanowires would block more light when it is used to fabricate a transparent conductive electrode (TCE) film. As a result, the optical transparency of the film is expected to reduce. Many efforts were taken in recent times to decrease the diameter of the silver nanowires by optimizing the other parameters, like the use of longer chain length PVP molecules Da Silva et al. (2016) or use of Br<sup>-</sup> ions (Zhang et al. 2018a), introducing benzoin-derived radicals Niu et al. (2018), high pressure (Jang et al. 2017) and N<sub>2</sub> gas environment synthesis Azani and Hassanpour (2019). The present work has explored manganese ions as the alternate oxygen scavenger to copper and iron ions without changing any other synthesis parameters.

### **4.3 Influence of Mn(II) Ions on the Growth of Silver Nanowires**

The Mn(II) ions are added during the synthesis of silver nanowires as the oxygen scavengers in place of copper ions to prevent the etching of twinned seed particles. It removes the atomic oxygen adsorbed on the surface of the silver seed particles. The effect of Mn(II) ions with a different concentration on the growth of silver nanowires is given in detail in this section.

Figure 4.10 a), b) show the FESEM micrograph of silver nanowires synthesised with the addition of 22 mM MnCl<sub>2</sub>. From the FESEM micrographs, it is observed that the synthesised products contained nanowires and very few particles. The average length of the nanowires was measured as 5.2 μm with the maximum length of 16 μm (Fig. 4.11). The average diameter of the nanowires was measured as 60 nm.

Figure 4.10 a), b) FESEM micrographs of the silver nanowires synthesised with the addition of 22 mM  $\text{MnCl}_2$

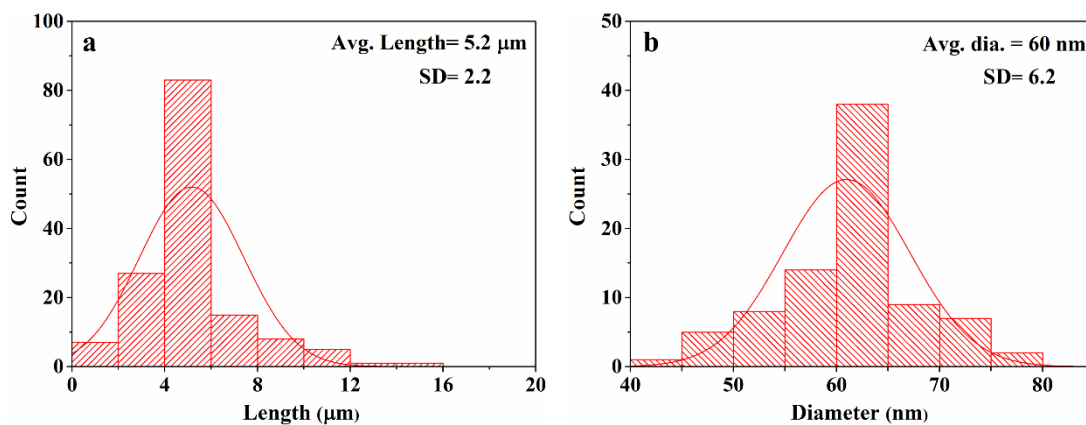

Figure 4.11 a), b) Length and diameter distribution of silver nanowires synthesised with the addition of 22 mM  $\text{MnCl}_2$

The average diameter of these nanowires is significantly smaller than the average diameter of nanowires (151 nm) synthesised with the addition of  $\text{CuCl}_2$  (Fig. 4.8 and 4.9). It should also be noted that the particles produced along with the nanowires were decreased considerably compared to that synthesised with the addition of  $\text{CuCl}_2$ . The decrease in the number of particles and the smaller diameter nanowires would minimize the light scattering that, in turn, enhance the optical transparency of the film fabricated with these silver nanowires. Moreover, the aspect ratio of the nanowires also will increase by decreasing the diameter of the nanowires. The silver nanowires with a high aspect ratio are essential to obtain highly transparent and conductive films.

Figure 4.12 a), b) FESEM micrographs of the silver nanowires synthesised with the addition of 40 mM  $\text{MnCl}_2$

Figure 4.13 a), b) Length and diameter distribution of silver nanowires synthesised with the addition of 40 mM  $\text{MnCl}_2$

Figure 4.12 shows the FESEM micrographs of silver nanowires synthesised with the addition of 40 mM concentration  $\text{MnCl}_2$ . The silver nanowires morphology is observed to be similar to that synthesised with the 22 mM concentration  $\text{MnCl}_2$ . However, it should be noted that the increased concentration of  $\text{MnCl}_2$  enlarged the length and diameter of the silver nanowires. The average length of 40 mM  $\text{MnCl}_2$  silver nanowires was measured as 7.7  $\mu\text{m}$  which is longer compared to 5.2  $\mu\text{m}$  (22 mM  $\text{MnCl}_2$  Ag NWs). The silver nanowires have grown up to the maximum length of 20  $\mu\text{m}$ . The length distribution of the nanowires is shown in Fig. 4.13a. Likewise, the corresponding diameter distribution is shown in Fig. 4.13b. It is observed that the average diameter of the 40 mM  $\text{MnCl}_2$  silver nanowires was measured as 80 nm which is relatively larger compared to that synthesised with the addition of 22 mM  $\text{MnCl}_2$ .

The FESEM micrographs of silver nanowires synthesised with the addition of 65 mM  $\text{MnCl}_2$  are shown in Fig. 4.14. When the concentration of the  $\text{MnCl}_2$  was increased from 40 mM to 65 mM, the length and diameter of the synthesised silver nanowires were reduced (Fig. 4.15).

Figure 4.14 a), b) FESEM micrographs of the silver nanowires synthesised with the addition of 65 mM  $\text{MnCl}_2$

Figure 4.15 a), b) Length and diameter distribution of silver nanowires synthesised with the addition of 65 mM  $\text{MnCl}_2$

The measured average length of the silver nanowires obtained from length distribution (Fig. 4.15a) was 6.3  $\mu\text{m}$  with a maximum length of 16  $\mu\text{m}$ . It is inferred that the further increase in the concentration of  $\text{MnCl}_2$  did not enhance the growth of the nanowires. The measured average diameter of the 65 mM  $\text{MnCl}_2$  silver nanowires was 71 nm (Fig. 4.15b).

In brief, the average diameter of the synthesised silver nanowires was measured as 60 nm, 80 nm and 71 nm for the  $\text{MnCl}_2$  concentration of 22 mM, 40 mM and 65 mM, respectively. Though the 40 mM sample is reported to have large diameter, its corresponding length is longer compared to other silver nanowires samples. The significance of the length and diameter of the silver nanowires can be well understood when they are shown in terms of aspect ratio (length to diameter).

Figure 4.16 Aspect ratio distributions of silver nanowires synthesised with the addition of  $\text{MnCl}_2$  of concentration a) 22 mM, b) 40 mM and c) 65 mM

The aspect ratio was calculated for the silver nanowires synthesised with the addition of three different  $\text{MnCl}_2$  concentration samples (Fig. 4.16). The calculated aspect ratio for silver nanowires synthesised with 22 mM, 40 mM and 65 mM  $\text{MnCl}_2$  was 81, 94 and 90, respectively. The mean aspect ratio of 40 mM concentration sample was the highest among all the silver nanowires samples. The high aspect ratio of silver nanowires will be beneficial to improve the percolation path, which in turn will increase the electrical conductivity of the silver nanowires film fabricated from this silver nanowires sample (Mutiso et al. 2013) (Jang et al. 2017). As the electrical percolation is achieved with the minimum number of silver nanowires, that would help to increase the optical transparency of the film (Jang et al. 2017).

Figure 4.17 Schematic shows the role of Mn(II) ions as the oxygen scavenger in preventing oxidative etching of the silver seeds

The schematic shown in Fig. 4.17 explains the influence of Mn(II) ions on the growth of the silver nanowires. During the synthesis, when  $\text{Ag}^+$  ions are reduced to  $\text{Ag}^0$  to form nuclei, the twins are formed due to thermal energy availability (Coskun et al. 2011). Multiply-twinned decahedra twins are the most stable and more favourable one to form. These multiply twinned particles (MTP) acts as the seeds for silver nanowires growth (Wiley et al. 2004). But this growth is often affected by the atomic oxygen, dissociated molecular oxygen from EG, adsorbed on these seed particles. The adsorbed oxygen would etch away the twinned seed particles. Also, it would block the surface of seed particles for the addition of new silver species (Wiley et al. 2004). This oxygen etching effect eventually results in the formation of nanocubes or short nanorods instead of nanowires (Wiley et al. 2004). When Mn(II) ions are introduced into the reaction through  $\text{MnCl}_2$ , the Mn(II) ions get oxidized to a higher oxidation state by absorbing the atomic oxygen from the surfaces of the seed particles. The oxidized manganese ions are subsequently reduced back to Mn(II) state by the ethylene glycol (Larcher et al. 2000). This oxidation and reduction process of Mn ions is continued to remove or scavenge the oxygen to prevent the etching of twinned particles. Thus, the twinned seed particles with active  $\{111\}$  sites remain available for the addition of new silver species.

When the Mn(II) ions absorb oxygen from the surface of silver seed particles, the following are the possible compounds to be formed, namely,  $\text{Mn}_3\text{O}_4$ ,  $\text{Mn}_2\text{O}_3$  and  $\text{MnO}_2$ . Among the oxides of Mn, the Gibbs free energy of formation ( $\Delta G_f^\circ$ ) for  $\text{Mn}_3\text{O}_4$  is more negative than other manganese oxide compounds. In the case of  $\text{CuCl}_2$ , the Cu(II) ions were first reduced to Cu(I) by ethylene glycol. Then it will move up to Cu(II) state by absorbing the atomic oxygen. Here, the CuO is the expected compound to be formed. The  $\Delta G_f^\circ$  for  $\text{Mn}_3\text{O}_4$  is  $-1288.23 \text{ kJ}\cdot\text{mol}^{-1}$ , whereas  $\Delta G_f^\circ$  for CuO is  $-129.7 \text{ kJ}\cdot\text{mol}^{-1}$ . Here, the  $\text{MnCl}_2$  and  $\text{CuCl}_2$  are the reactants,  $\text{Mn}_3\text{O}_4$  and CuO are their corresponding products. The  $\Delta G_f^\circ$  for oxygen scavenging is calculated as,

$$\Delta G_f^\circ \text{ of } (\text{MnCl}_2 \rightarrow \text{Mn}_3\text{O}_4) = -1288.23 \text{ kJ}\cdot\text{mol}^{-1} - (-440.53 \text{ kJ}\cdot\text{mol}^{-1}) = -847.7 \text{ kJ}\cdot\text{mol}^{-1}$$

$$\Delta G_f^\circ \text{ of } (\text{CuCl}_2 \rightarrow \text{CuO}) = -129.704 \text{ kJ}\cdot\text{mol}^{-1} - (-161.92 \text{ kJ}\cdot\text{mol}^{-1}) = 32.216 \text{ kJ}\cdot\text{mol}^{-1}$$

The more negative of  $\Delta G_f^\circ$  of  $(\text{MnCl}_2 \rightarrow \text{Mn}_3\text{O}_4)$  indicates that the process of oxygen scavenging is more spontaneous than that observed by using Cu(II) ions. In other words, the tendency to absorb oxygen from the surface of silver seed particles is higher for the Mn(II) ions compared to the Cu(I) ions.

#### 4.4 UV-VIS Absorption Spectroscopy of Synthesised Silver Products

Figure 4.18 UV-VIS absorption spectra of silver products synthesised with three different chloride conditions

Figure 4.18 shows the UV-VIS absorption spectra of the silver particles synthesised without any chloride salt, silver nanowires synthesised with the addition of  $\text{CuCl}_2$  (22 mM) and  $\text{MnCl}_2$  (22 mM). The absorption spectrum of silver particles showed a broad absorption peak at 450 nm. The silver nanowires exhibited a predominant peak along with a low-intensity peak. The  $\text{CuCl}_2$  sample showed maximum absorption at 389 nm while the  $\text{MnCl}_2$  sample exhibited the maximum absorption at 382 nm. The existence of these observed peaks was due to the surface plasmon resonance (SPR) of silver nanostructures (Ma and Zhan 2014). The SPR peak at 450 nm is attributed to the large particle size of silver (Wiley et al. 2005). However, the maximum absorption was blue-shifted for the nanowires. This is because the surface plasmon resonance becomes dominant in the transverse direction (Ma and Zhan 2014). The blue-shift from 389 nm to 382 nm is attributed to the decrease in the diameter of nanowires from 151 nm to 60 nm (Niu et al. 2018).

Figure 4.19 UV-VIS absorption spectra of silver nanowires synthesised with the addition of different concentrations of  $\text{MnCl}_2$

The absorption peak shift was also observed for the silver nanowires synthesised with different  $\text{MnCl}_2$  concentrations (Fig. 4.19). The 22 mM sample with a mean diameter of 60 nm exhibited the absorption peak at 382 nm. But the absorption was red-shifted to 387 nm for the 40 mM sample because of its larger diameter of 80 nm. This red-shift

of SPR peak with respect to increased diameter was attributed to the inhomogeneous polarization caused by multipolar oscillations in silver nanowires due to the large diameter (Ma and Zhan 2014) (Amendola et al. 2017). The absorption peak was blue-shifted to 384 nm for the 65 mM sample due to decrease in the diameter to 71 nm from 80 nm. The change in the absorption wavelength corresponding to the concentration of the  $\text{MnCl}_2$  again confirms the influence of  $\text{Mn(II)}$  ions on the diameter of the silver nanowires (Ma and Zhan 2014) (Niu et al. 2018).

#### 4.5 Transmission electron microscopy of synthesised silver products

Figure 4.20 TEM micrograph of the Ag nanoparticles synthesised with the addition of no chloride salt

The TEM micrograph of silver nanoparticle synthesised without any chloride addition is shown in Fig. 4.20. The micrograph reveals the spherical-like morphology of this silver nanoparticle. This nanoparticle is, in fact, the aggregation of small silver nanoparticles. The measured size of this aggregated nanoparticle is 160 nm. The TEM result complements the FESEM result to confirm the growth of silver nanoparticles when it was synthesised without the presence of any chloride salts. As mentioned earlier, the rapid reduction of  $\text{Ag}^+$  ions to  $\text{Ag}^0$  without any buffer phase for the controlled release of silver was the reason behind the growth of silver particles (Coskun et al. 2011).

Figure 4.21 TEM micrograph of silver nanorod synthesised with the addition of NaCl

Figure 4.22 TEM micrograph of silver nanocube synthesised with the addition of NaCl

Figure 4.23 The SAED pattern of silver nanocube synthesised with the addition of NaCl

Figure 4.21 shows the TEM micrograph of silver nanorod synthesised with the addition of NaCl. The length and diameter of the nanorods were measured as 790 nm and 77 nm, respectively. The presence of twin boundaries in the nanorod is seen parallel to its axis. When  $\text{Cl}^-$  ions were introduced through the addition of NaCl, they prevented the formation of aggregated particles and promoted one-dimensional growth (Coskun et al. 2011). But the presence of atomic oxygen hindered the growth of the one-dimensional growth as mentioned earlier. It resulted in the short nanorods. Figure 4.22 shows the TEM micrograph of nanocube produced along with the silver nanorod as a by-product during the synthesis process. It is observed that this nanocube does not show any evidence for the presence of the twins in its structure (Wiley et al. 2005). The corresponding SAED pattern of this nanocube (Fig. 4.23) confirms the absence of twins. From the above observation, it is concluded that the oxidative etching of the twins was the reason for the growth of short nanorods and nanocubes.

Figure 4.24 TEM micrograph of silver nanowire synthesised with 22 mM of  $\text{MnCl}_2$

Figure 4.25 The SAED pattern of silver nanowire synthesised with 22 mM of  $\text{MnCl}_2$

Fig. 4.24 shows the TEM micrograph of silver nanowire synthesised with the addition of 22 mM  $\text{MnCl}_2$ . The diameter of the nanowire was measured as 50 nm. The micrograph reveals the presence of the twin boundaries along the longitudinal axis of the nanowire. These twin boundaries are the highest energy sites that attract the new incoming silver species to grow on them during the synthesis process. This selective growth of silver on the twin boundaries leads to one-dimensionally grown nanowires.

The selected area electron diffraction (SAED) pattern shown in Fig. 4.25 also confirmed the presence of twins in the silver nanowire. Two different sets of diffraction patterns with the zone axis of [011] and [111] were observed. The existence of two sets of diffraction in the SAED pattern is supported by the previous literatures Wang et al. (2016b).

#### 4.6 X-Ray Diffraction Study

Figure 4.26 XRD pattern of silver nanoparticles synthesised without any chloride salt

Figure 4.26 shows the XRD pattern of silver nanoparticles synthesised without any chloride salt during the synthesis process. The XRD pattern exhibit two peaks which are corresponding to (111) and (200) planes of silver (ICDD 04-0783).

Figure 4.27 XRD pattern of silver nanowires synthesised with the addition of different chloride salts

The XRD patterns of silver nanowires synthesised with the addition of NaCl, CuCl<sub>2</sub> and MnCl<sub>2</sub> are shown in Fig. 4.27. The XRD patterns of the mentioned three samples show peaks corresponding to (111), (200) planes of silver (ICDD 04-0783). The highest peak intensity of the (111) plane is attributed to the preferred (111) plane growth of silver nanowires.

#### 4.7 Opto-Electric Properties of Silver Nanowires Films

The network of silver nanowires in the fabricated silver nanowires film forms a percolation path for electrical conductivity through the junctions of nanowires. Although the wire-wire junctions help to form the percolation path, the electrical conductivity of the silver nanowires film is dropped by the resistance at the wire-wire junctions (Langley et al. 2014). In other words, the sheet resistance of the film is increased with the increase in wire-wire junctions. This is the reason for the importance of using longer silver nanowires with a high aspect ratio. The electrical percolation is achieved with fewer wire-wire junctions by using longer nanowires (Madeira et al. 2020). Thus, the sheet resistance of the film can be reduced. The encapsulation of silver nanowires with PVP molecules is another factor that increases the sheet resistance (Langley et al. 2014). The above two problems could be resolved by annealing the

fabricated silver nanowires film. Annealing the films below the fragmentation temperature of silver nanowires leads to melting of PVP molecules from the surface of the silver nanowires and fusing of nanowires at the wire-wire junctions. The resistance at wire-wire junctions is reduced by fusion of nanowires that would reduce the overall sheet resistance of nanowires film (Langley et al. 2014).

The sheet resistance of films fabricated from silver nanowires synthesised with the addition of  $\text{MnCl}_2$  was measured before and after the annealing process. The fabricated films were subjected to annealing at  $165\text{ }^\circ\text{C}$  for 30 minutes. The sheet resistance values of the films determined from the four-probe measurement are given in Table 4.1. It is observed that the sheet resistance of the silver nanowires film was reduced significantly after the annealing process.

Table 4.1 Sheet resistance of silver nanowires film: before and after annealing treatment

No. of coating layers	Ag NWs film (22 mM $\text{MnCl}_2$ )		Ag NWs film (40 mM $\text{MnCl}_2$ )		Ag NWs film (65 mM $\text{MnCl}_2$ )	
	$R_s$ (before annealing) $\Omega/\text{sq}$	$R_s$ (after annealing) $\Omega/\text{sq}$	$R_s$ (before annealing) $\Omega/\text{sq}$	$R_s$ (after annealing) $\Omega/\text{sq}$	$R_s$ (before annealing), $\Omega/\text{sq}$	$R_s$ (after annealing) $\Omega/\text{sq}$
4L	2700	485	1900	332	2180	395
5L	55	40	42	29	48	34
6L	38	20	23	11	31	15
7L	22	16	12	7.5	17	11
8L	14	7	10	4	10	5

As high optical transparency and high electrical conductivity are the desirable characteristics of a good transparent conductive electrode, it is imperative to correlate these two factors. The desirable silver nanowires film should have high optical

transmittance at the wavelength of 550 nm ( $\%T_{550\text{nm}}$ ) with low sheet resistance ( $R_s$ ). The ' $\%T_{550\text{nm}}$ ' and ' $R_s$ ' of the films are changed with the number of silver nanowires coating layers.

Figure 4.28, 4.29 and 4.30 show the UV-VIS transmittance spectra of the films prepared using silver nanowires synthesised with three different concentrations of  $\text{MnCl}_2$  (22 mM, 40 mM and 65 mM, respectively). The films prepared by using 22 mM, 40 mM and 65 mM samples are named as M22, M40 and M65 respectively. The spray coating method was followed to prepare the multilayer (4L, 5L, 6L, 7L and 8L) silver nanowires films. The density of the silver nanowires in the film was increased with respect to the number of spray-coated silver nanowires layers. It is observed that the optical transparency of the film was decreased with the number of coating layers. The increase in nanowires density in the film caused to decrease in the light transmittance through the films. Nevertheless, the increase in density of nanowires improved the electrical percolation in the film. It is evident from the reduction in sheet resistance of the film with the increasing the number of coating layers of silver nanowires.

Figure 4.28 Optical transmittance and sheet resistance of M22 silver nanowires films

Figure 4.28 shows the transmittance spectra of M22 silver nanowires films with their corresponding sheet resistance ( $R_s$ ) values. The transmittance at  $\lambda=550$  nm ( $\%T_{550\text{nm}}$ ) and  $R_s$  values of 4L, 5L, 6L, 7L and 8L films were determined as 90%, 81%, 72%, 62%,

55% and 485, 40, 20, 16 and 7  $\Omega/\text{sq}$ , respectively. With high  $R_s$  (4L film) of 485  $\Omega/\text{sq}$  and low  $\%T_{550\text{ nm}}$  of less than 75%, the films other than 5L are not suitable to be used as TCE. The 5L film is the best TCE among M22 silver nanowires films with the optical transmittance ( $\%T_{550\text{ nm}}$ ) of 81% and sheet resistance of 40  $\Omega/\text{sq}$ .

Figure 4.29 Optical transmittance and sheet resistance of M40 silver nanowires films

Fig. 4.29 shows the opto-electrical characteristics of M40 (40 mM  $\text{MnCl}_2$ ) silver nanowires films. The  $\%T_{550\text{ nm}}$  and  $R_s$  values of 4L, 5L, 6L, 7L and 8L films were determined as 87%, 79%, 69%, 58%, 52% and 332, 29, 11, 7.5 and 4  $\Omega/\text{sq}$ , respectively. Among all M40 silver nanowires films (4L, 5L, 6L, 7L and 8L), 5L silver nanowires film with  $\%T_{550\text{ nm}}=79\%$  and  $R_s=29\ \Omega/\text{sq}$ . was acceptable with the balanced transmittance and sheet resistance values.

Figure 4.30 Optical transmittance and sheet resistance of M65 silver nanowires films

Fig. 4.30 shows the optical transmittance spectra of M65 silver nanowires film with their corresponding sheet resistance. The % $T_{550\text{ nm}}$  and  $R_s$  values of 4L, 5L, 6L, 7L and 8L films were found to be 88.5%, 80%, 71%, 60%, 54% and 395, 34, 15, 11 and 5  $\Omega/\text{sq}$ , respectively. Among these films, the 5L silver nanowires film showed acceptable transmittance and sheet resistance values of % $T_{550\text{ nm}}=80\%$  and  $R_s=34\ \Omega/\text{sq}$ .

The figure-of-merit (FOM) is the widely accepted quantitative expression that defines the quality of a transparent conductive electrode film. The figure-of-merits ( $\phi_{\text{TC}}$ ) is calculated by using the formula given by Haacke (Haacke 1976),

$$\phi_{\text{TC}} = T^{10}/R_s \quad (3)$$

The term ‘ $T$ ’ and ‘ $R_s$ ’ denote the optical transmittance and the sheet resistance of the film, respectively. The FOM values of 5L films from each set of films (M22, M40 and M65) were calculated by using the above formula (1). The calculated FOM values are plotted against their corresponding % $T_{550\text{ nm}}$ , in Fig. 4.31.

Figure 4.31 Figure of merits of M22, M40 and M65 silver nanowires films

The maximum value of  $0.00327 \Omega^{-1}$  was reported for the 5L-M40 film. The FOM value of 5L-M65 and 5L-M22 were reported as  $0.00316 \Omega^{-1}$  and  $0.00304 \Omega^{-1}$ , respectively. The figure of merit is also represented as the ratio of electrical to optical conductivity ( $\sigma_{DC}/\sigma_{OP}$ ). The  $\sigma_{DC}/\sigma_{OP}$  ratio was calculated using the formula (Sepulveda-Mora and Cloutier 2012),

$$T = (1 + [188.5/R_s] \cdot (\sigma_{OP} / \sigma_{DC}))^{-2} \quad (4)$$

The calculated  $\sigma_{DC}/\sigma_{OP}$  ratio for 5L-M22, 5L-M40 and 5L-M65 are  $42.4 \Omega^{-1}$ ,  $52 \Omega^{-1}$  and  $47 \Omega^{-1}$ , respectively. The maximum FOM values calculated from the above two formula belonged to the 5L-M40 film. Although the large diameter factor of silver nanowires (40 mM sample) caused a reduction in the optical transmittance of the M40 sample to 79%, the lowest sheet resistance of  $29 \Omega/\text{sq}$  was obtained due to the increased length of nanowires. The use of longer silver nanowires improved the percolation path while reducing the wire to wire contact resistance in the film. That eventually leads to high FOM value.

Figure 4.32 Camera image of the silver nanowires film (5L-M40) deposited on a plastic sheet

The camera captured image of the 5L layers coated silver nanowires films (M40) spray-coated on a plastic substrate is shown in Fig. 4.32. The optical transparency of the prepared silver nanowires film can be compared with the background of the film.

#### 4.8 Mechanical Flexibility Study

Figure 4.33 Change in the sheet resistance value of silver nanowires film and ITO film against the number of bending cycles

The mechanical flexibility and stability without losing its electrical conductivity are essential properties for a flexible transparent conductive electrode. The silver nanowires spray-coated on a plastic sheet (shown in Fig. 4.32) was subjected to a bending test. A commercial ITO coated on PET sheet (Sigma-Aldrich) was also subjected to the same bending test for the comparison purpose. The percentage change in the sheet resistance of both films with respect to the bending cycles is shown in Fig. 4.33. The sheet resistance of the ITO film was increased up to 275% from its original value after 280 numbers of bending cycles. On the other hand, the silver nanowires film showed better stability with only 14% increase in sheet resistance from its original value after 500 cycles of bending.

#### **4.9 Heater Test**

Apart from solar cells and displays, the transparent conducting electrode also finds its application as the transparent heaters. It is used to fabricate anti-fogging and anti-frost front window panels for vehicles and aircraft (Tiwari et al. 2017).

The 5L silver nanowires film of sets M22, M40 and M65 with the sheet resistance of 40, 29 and 34  $\Omega/\text{sq}$  respectively, were tested for the heater application. The heater test was conducted at the applied voltage of 5, 7 and 10 V. The temperature response to the applied voltage was recorded at the time interval of 15 seconds. The temperature vs. time profiles of M22 silver nanowires film corresponding to applied voltages is shown in Fig. 4.34.

Figure 4.34 Temperature vs. time curve of silver nanowires film synthesised with 22 mM MnCl<sub>2</sub> (M22) to the applied voltage values of 5, 7 and 10 V

The 5L film of M22 silver nanowires film was tested for heater application with the applied voltage of 5, 7 and 10 V. The silver nanowires film reached the maximum temperature of 36.5 °C, 43.5 °C and 62 °C for the applied voltage of 5, 7 and 10 V, respectively.

Figure 4.35 Temperature vs. time curve of silver nanowires film synthesised with 40 mM MnCl<sub>2</sub> (M40) at applied voltage values of 5, 7 and 10 V

The temperature response of the 5 L film of M40 silver nanowires to the applied voltage are shown in Fig. 4.35. The maximum temperature achieved by the silver nanowires film was 44 °C, 65.5 °C and 90 °C to the applied voltage of 5, 7 and 10 V, respectively. The enhanced heater performance of this M40 silver nanowires film compared to the M22 silver nanowires film is due to the decreased sheet resistance (29 Ω/Sq.) of the film (Park et al. 2019).

Figure 4.36 Temperature vs. time curve of silver nanowires film synthesised with 65 mM MnCl<sub>2</sub> (M65) at applied voltage values of 5, 7 and 10 V

Figure 4.36 shows the temperature response of 5L-M65 silver nanowires film to the applied voltages of 5, 7 and 10 V. The silver nanowires film with the sheet resistance of 34 Ω/sq. achieved the maximum temperature of 41 °C, 53 °C and 74 °C for the applied voltage of 5, 7 and 10 V. The maximum temperature of 74 °C is in between the temperature achieved by the M22 and M40 silver nanowires films. The intermittent sheet resistance value of this film (34 Ω/sq.) was the reason for this temperature value.

In short, the silver nanowires film of  $R_s=40 \Omega/\text{sq}$  attained the maximum temperature of 62 °C in 300 seconds at the applied voltage of 10 V. While the silver nanowires film of 34 Ω/sq reached higher temperature of 74 °C for the same voltage. But the highest temperature of 90 °C was attained by the silver nanowires film of  $R_s=29 \Omega/\text{sq}$  at the voltage of 10 V. It is observed that the maximum temperature achieved by the silver

nanowires film can be increased by increasing the applied voltage and time of voltage supply. Also, it is observed that the reduction in sheet resistance improves the heater performance of the film (Park et al. 2019). The influence of sheet resistance on heat energy produced is related by Joule's law as given below (Ha and Jo 2017),

$$Q = (V^2/R).t \quad (5)$$

Where 'Q' is heat generated, 'V' represents the applied voltage value, 'R' is sheet resistance and 't' is time. The heat generated by the film is inversely proportional to the sheet resistance of the film.

#### **4.10 Summary**

The silver nanowires were synthesised by the polyol method. It is understood that the presence of chloride ions is essential to form the AgCl buffer phase that promotes the one-dimensional growth of silver nanostructures. The manganese(II) ions were used during the synthesis as the oxygen scavenger as the alternative to copper ions. It is proved that the Mn(II) ions were effective in removing the atomic oxygen from the surface of the silver to enhance the growth of nanowires. The silver nanowires synthesised with the addition of MnCl<sub>2</sub> showed a smaller diameter of 60 nm than the silver nanowires produced with CuCl<sub>2</sub> (151 nm). The optimum condition of 40 mM MnCl<sub>2</sub> yielded long silver nanowires with a small diameter compared to the CuCl<sub>2</sub> condition. The silver nanowires film fabricated using 40 mM MnCl<sub>2</sub> silver nanowires showed the optical transmittance (%T<sub>550 nm</sub>) of 79% and R<sub>s</sub> of 29 Ω/sq. The bending test result shows that the flexible transparent conductive film of silver nanowires coated on the plastic sheet is mechanically stable. Unlike commercial ITO film, the sheet resistance of the nanowires film increased little after 500 cycles of bending. The heater test showed that the silver nanowires film could reach a temperature of 90 °C for the applied voltage of 10 V.

## CHAPTER 5

### SYNTHESIS AND CHARACTERIZATION OF MoS<sub>2</sub> NANOSHEETS

*This chapter presents the exfoliation of MoS<sub>2</sub> nanosheets by ultrasonication-assisted liquid phase exfoliation method. The exfoliated nanosheets are characterized by using electron microscopy (FESEM, TEM), X-ray diffractometry, Raman spectroscopy and BET analysis.*

#### 5.1 Exfoliation of MoS<sub>2</sub> Nanosheets

Figure 5.1 a), b) FESEM micrographs of the bulk MoS<sub>2</sub> powder

Figure 5.1 show the FESEM micrograph of the bulk MoS<sub>2</sub> powder. It is observed that the bulk powder consisted of several layers of the MoS<sub>2</sub> stacked one above the other. The size of the bulk MoS<sub>2</sub> powder particles was varying from 150 nm to more than 1 μm. The dimensions of the particles were measured using ImageJ software

Figure 5.2 a), b) FESEM micrographs of the exfoliated MoS<sub>2</sub> nanosheets

Figure 5.2 show the FESEM micrographs of the exfoliated MoS<sub>2</sub> nanosheets. The FESEM micrograph of exfoliated nanosheets revealed that the thicker bulk MoS<sub>2</sub> powders were reduced into thin nanosheets. The MoS<sub>2</sub> layers were peeled off by the shear force induced from the ultrasonication process. The van der Waals force of interactions that held the MoS<sub>2</sub> layers together was overcome by this shear force (Gupta et al. 2016). That helped in the exfoliation process of MoS<sub>2</sub> nanosheets. The PVP

molecules played a vital role to passivate the exfoliated nanosheets to prevent them from restacking (Liu et al. 2012).

Figure 5.3 a), b) TEM micrographs of the exfoliated MoS<sub>2</sub> nanosheets

Figure 5.3 shows the TEM micrograph of the exfoliated MoS<sub>2</sub> nanosheets. It is observed that the exfoliated MoS<sub>2</sub> nanosheets consist of only a few layers. The size of the MoS<sub>2</sub> nanosheets was also reduced after the ultrasonic exfoliation. The size of the nanosheets is measured to be in the range of 60 nm to 400 nm.

Figure 5.4 a) Lattice image of the MoS<sub>2</sub> nanosheet, b) Crystal structure of MoS<sub>2</sub>

Figure 5.5 SAED pattern of the exfoliated MoS<sub>2</sub> nanosheet

The lattice distance of 0.27 nm is measured from the high-resolution TEM micrograph shown in Fig. 5.4. It is attributed to the (100) plane of MoS<sub>2</sub>. Figure 5.5 shows the SAED pattern of the MoS<sub>2</sub> nanosheet. The SAED pattern reveals the hexagonal lattice structure of the MoS<sub>2</sub> nanosheets.

## 5.2 X-Ray Diffractrometry

Figure 5.6 XRD patterns of the bulk MoS<sub>2</sub> powder and the exfoliated MoS<sub>2</sub> nanosheets

The XRD patterns of bulk MoS<sub>2</sub> powder and exfoliated MoS<sub>2</sub> nanosheets are shown in Fig. 5.6. The XRD pattern of both materials belongs to the Molybdenite-2H phase (ICDD #006-0097). The maximum intensity was observed for the peak belonged to the (002) plane for both materials. But the peaks of (103) and (105) planes that appeared for the bulk powder were absent for the exfoliated nanosheets. Also, the peak of (002) plane was broader for the exfoliated nanosheets compared to the bulk powder. This indicates the reduction in the crystal thickness of MoS<sub>2</sub> after the exfoliation process (Wang et al. 2015). The broad amorphous peak appeared between 20° to 35° was due to the glass substrate.

The texture coefficient was calculated for the bulk and exfoliated MoS<sub>2</sub> from their corresponding XRD data. The texture coefficient (T.C) was calculated by using the following formula (Sneha et al. 2017),

$$T.C_{(hkl)} = \frac{I_{(hkl)}}{I_{(002)} + I_{(004)} + I_{(103)} + I_{(006)} + I_{(105)}}$$

Here, (hkl) represents (002) or (004) or (103) or (006) or (105) planes. ‘I’ represents the intensity of the individual XRD peaks.

Figure 5.7 Texture coefficient of the bulk MoS<sub>2</sub> powder and the exfoliated MoS<sub>2</sub> nanosheets

Figure 5.7 shows the texture coefficient of the bulk MoS<sub>2</sub> powder and the exfoliated MoS<sub>2</sub> nanosheets. In the case of bulk MoS<sub>2</sub>, it is noted that the texture coefficient of planes (002), (004), (103), (105) and (006) is 0.66, 0.044, 0.054, 0.175 and 0.068, respectively. For MoS<sub>2</sub> nanosheets, the texture coefficient for planes (002), (004) and (006) was calculated as 0.67, 0.2 and 0.14, respectively. The texture coefficient for (103) and (105) planes are negligible since the XRD peaks were not observed for these planes. The texture coefficient of (002) and (004) planes was increased after the exfoliation process. The absence of peaks belonged to (103) and (105) planes for the exfoliated MoS<sub>2</sub> nanosheets increased the texture coefficient values for (002) planes.

### 5.3 Raman Spectroscopy

Figure 5.8 Raman spectra of bulk MoS<sub>2</sub> powder and exfoliated MoS<sub>2</sub> nanosheets

The Raman spectra of bulk MoS<sub>2</sub> and MoS<sub>2</sub> nanosheets are shown in Fig. 5.8. The characteristic Raman vibration peaks of E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> for bulk MoS<sub>2</sub> are observed at 383 cm<sup>-1</sup> and 407 cm<sup>-1</sup>, respectively (Rao et al. 2017). When the thickness of the MoS<sub>2</sub> sheet decreases, the E<sub>2g</sub><sup>1</sup> peak belonging to the in-plane sulfur-molybdenum vibration shifts to a higher frequency, whereas the A<sub>1g</sub> peak belonging to the out-plane sulfur vibration shifts to a lower frequency (Rao et al. 2017). The exfoliated MoS<sub>2</sub> nanosheets exhibited E<sub>2g</sub><sup>1</sup> and A<sub>1g</sub> peaks at 384 cm<sup>-1</sup> and 405.5 cm<sup>-1</sup>, respectively. The frequency gap between two Raman peaks of the exfoliated MoS<sub>2</sub> nanosheets was reduced to 21.5 cm<sup>-1</sup> from 24 cm<sup>-1</sup>. This is the indication that the bulk MoS<sub>2</sub> was exfoliated to nanosheets with few layers thickness (Tsai et al. 2014).

## 5.4 Specific Surface Area Analysis

Figure 5.9 Nitrogen adsorption-desorption curve of MoS<sub>2</sub> nanosheets

Figure 5.10 Pore size distribution of MoS<sub>2</sub> nanosheets

Figure 5.9 shows the Nitrogen adsorption-desorption curve of exfoliated MoS<sub>2</sub> nanosheets. The adsorption-desorption isotherm with a small hysteresis loop indicates that the isotherm is a type IV isotherm defined by the IUPAC (Fan et al. 2015). The

pore size distribution curve shows (Fig. 5.10) the peaks at the pore size of 6.2 nm, 8.2 nm and 14 nm with the mean pore size of 7.7 nm. This indicates the mesoporous nature of the dried MoS<sub>2</sub> nanosheets powder (Fan et al. 2015). The specific surface area (S<sub>a</sub>) of the MoS<sub>2</sub> nanosheets measured by the BET method was 17.5 m<sup>2</sup> g<sup>-1</sup>. This S<sub>a</sub> value of MoS<sub>2</sub> nanosheets was marginally larger than the previously reported values (Fan et al. 2015) (Qiao et al. 2016). The MoS<sub>2</sub> nanosheets with a high specific surface area are crucial to increase the specific capacity when they are used for energy storage applications.

## 5.5 Summary

The MoS<sub>2</sub> nanosheets were exfoliated via ultrasonication-assisted liquid phase exfoliation method in the presence of PVP. The shear forces and the mechanical agitation induced by the ultrasonication peeled off the bulk MoS<sub>2</sub> powder into MoS<sub>2</sub> nanosheets. The stability of the exfoliated nanosheets were maintained by the dissolved PVP molecules. The exfoliated MoS<sub>2</sub> nanosheets remained suspended in the dispersion with minimum precipitation at the bottom of the vial after a week time. The FESEM and TEM characterizations manifested that the exfoliated MoS<sub>2</sub> contained few layers of nanosheets. It was confirmed by the Raman spectroscopy results. The XRD analysis established the nature of the exfoliated nanosheets as MoS<sub>2</sub>. The exfoliated MoS<sub>2</sub> nanosheets showed a good specific surface area of 17 m<sup>2</sup> g<sup>-1</sup>.

## CHAPTER 6

### PREPARATION AND CHARACTERIZATION OF MoS<sub>2</sub>-SnO<sub>2</sub> NANOCOMPOSITE FOR THE SUPERCAPACITOR APPLICATION

*The present chapter discusses the synthesis of SnO<sub>2</sub> nanoparticles, preparation of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite and their various materials characterization, such as FESEM, TEM, particle size analysis, XRD and XPS. The electrochemical characterization of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite is also discussed in this chapter.*

#### 6.1 Preparation and Characterization of MoS<sub>2</sub>-SnO<sub>2</sub> Nanocomposite

Figure 6.1 FESEM micrograph of the SnO<sub>2</sub> nanoparticles

The FESEM micrograph of synthesised SnO<sub>2</sub> nanoparticles is shown in Fig. 6.1. It is observed that the synthesised SnO<sub>2</sub> nanoparticles have spherical-like morphology. The size of the synthesised nanoparticles was in the range of 10-35 nm. The TEM micrographs of the synthesized SnO<sub>2</sub> nanoparticles showed in Fig. 6.2 affirm the spherical-like morphology of the synthesised product. The lattice distances of 0.34 nm and 0.26 nm were measured from the TEM micrograph (Fig. 6.2b). There were belonged to the (110) and (101) planes of SnO<sub>2</sub>, respectively.

Figure 6.2 TEM micrographs of the SnO<sub>2</sub> nanoparticles

Figure 6.3 Particle size distribution of the SnO<sub>2</sub> nanoparticles

Figure 6.3 shows the particle size distribution chart of the SnO<sub>2</sub> nanoparticles obtained from the particle analysis test. It is observed that the average size of the synthesised SnO<sub>2</sub> nanoparticles was measured as 17.7 nm (standard deviation= 4.2). Almost 90%

of the particles fall in size range of 10-21 nm, while the rest of the particles fall in the size range of 25-37 nm.

Figure 6.4 FESEM micrograph of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

Figure 6.4 shows the FESEM micrograph of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite prepared by the ligand exchange process. The MoS<sub>2</sub> nanosheets exfoliated in the presence of PVP were added to the SnO<sub>2</sub> nanoparticles. The ammonium ions coordinated with SnO<sub>2</sub> nanoparticles replaced the PVP molecules attached with the surface of MoS<sub>2</sub> nanosheets. Thus, the SnO<sub>2</sub> nanoparticles were functionalized onto the surface of the exfoliated MoS<sub>2</sub> nanosheets. The SnO<sub>2</sub> nanoparticles were firmly attached to the surface of the MoS<sub>2</sub> nanosheets. Figure 6.5 shows the schematic diagram explaining the functionalization of MoS<sub>2</sub> nanosheets with SnO<sub>2</sub> nanoparticles by the ligand exchange process.

A thin layer of PVP molecules, from the exfoliation step, would still present onto the surface of the MoS<sub>2</sub> nanosheets even after the washing process because of C-S and O-S bonding between PVP and MoS<sub>2</sub> (Liu et al. 2018). Also, this PVP ligand attached with MoS<sub>2</sub> nanosheets kept nanosheets separated from each other. On the other hand, ammonium ions from ammonium salts coordinated with the SnO<sub>2</sub> nanoparticles during the synthesis process. These ammonium ions act as the surfactant to control the growth of the nanoparticles (Bob et al. 2016).

Figure 6.5 Schematic diagram explains the functionalization of MoS<sub>2</sub> nanosheets with SnO<sub>2</sub> nanoparticles

When the MoS<sub>2</sub> nanosheets are added into SnO<sub>2</sub> nanoparticles (Fig. 3.7), the ammonium ions attached with the SnO<sub>2</sub> nanoparticles strip off the PVP molecules from the surface of the MoS<sub>2</sub> nanosheets. Subsequently, the vacant sites left by the stripped PVP molecules were occupied by the SnO<sub>2</sub> nanoparticles. The ammonium ions present over the SnO<sub>2</sub> nanoparticles would help them to anchor onto the surface of the MoS<sub>2</sub> nanosheets (Bob et al. 2016). Likewise, the SnO<sub>2</sub> nanoparticles were decorated or functionalized on the surface of the MoS<sub>2</sub> nanosheets. Bob et al. (2016) also reported this ligand exchange process to deposit SnO<sub>2</sub> nanoparticles on the silver nanowires surface. When mixing the dispersion of silver nanowires and SnO<sub>2</sub> nanoparticles together, the SnO<sub>2</sub> nanoparticles get coated on the silver nanowires by stripping and replacing the PVP molecules from the nanowires through ammonia ions.

This functionalization process by exchanging the ligands is energy efficient compared to the hydrothermal method which involves high temperature and pressure (Ren et al. 2015). Once the PVP molecules were replaced by SnO<sub>2</sub> nanoparticles on the MoS<sub>2</sub> surface, the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite started to settle down as the precipitate (Fig. 3.7; Chapter 3). After removing the supernatant containing PVP molecules, the obtained residue was used for further studies.

Figure 6.6 TEM micrographs of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

Figure 6.6 shows the TEM micrographs of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite prepared by the ligand exchange process. The SnO<sub>2</sub> nanoparticles could be seen functionalized on the surface of the MoS<sub>2</sub> nanosheets. The MoS<sub>2</sub> nanosheets can act as the bridge between the SnO<sub>2</sub> nanoparticles.

Figure 6.7 XRD patterns of the MoS<sub>2</sub> nanosheets, SnO<sub>2</sub> nanoparticles and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

Figure 6.7 shows the XRD patterns of the SnO<sub>2</sub> nanoparticles and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite along with the MoS<sub>2</sub> nanosheets. Three peaks were observed at angles 26.2°, 33.8° and 51.2° for SnO<sub>2</sub> nanoparticles which are attributed to the planes (110), (101) and (211), respectively, of SnO<sub>2</sub> (Cassiterite, ICDD #041-1445). The XRD pattern of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite exhibited the peaks of both SnO<sub>2</sub> and MoS<sub>2</sub> phases.

Figure 6.8 a) XPS spectrum of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite and high resolution XPS spectrum of b) Mo 3d, c) Sn 3d, d) S 2p

From the XPS survey spectrum of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite (Fig. 6.8a), the presence of peaks corresponding to Mo, Sn, S, O, N and C elements were observed. The high-resolution XPS spectrum of Mo 3d region (Fig. 6.8b) exhibited two peaks at the binding energies 229.4 and 232.4 eV which are belonged to 3d<sub>5/2</sub> and 3d<sub>3/2</sub>, respectively. These binding energies were corresponding to the +4 oxidation state of Mo. Also, a broad

peak corresponding to S 2s was observed at 226.5 eV in the same spectrum. The high-resolution XPS spectrum of Sn 3d region is shown in Fig. 6.8c. Two peaks at 487.4 and 495.8 eV were observed. These were belonged to 3d<sub>5/2</sub> and 3d<sub>3/2</sub> of Sn (+4 oxidation state), respectively. The XPS spectrum of S is shown in Fig. 6.8d. The XPS spectrum of S 2p region was resolved into a doublet peak, with the binding energies 162.2 and 163.2 eV corresponding to 2p<sub>3/2</sub> and 2p<sub>1/2</sub> of S, respectively. This peak deconvolution was done considering the spin-orbit coupling rule. The above results confirm the presence of MoS<sub>2</sub> and SnO<sub>2</sub> without any other oxidation products (Chen et al. 2014).

## **6.2 Electrochemical Characterization of MoS<sub>2</sub>-SnO<sub>2</sub> Nanocomposite for the Supercapacitor Application**

The specific surface area of MoS<sub>2</sub> nanosheets is large (17.5 m<sup>2</sup> g<sup>-1</sup>). The conductivity of MoS<sub>2</sub> nanosheet is better than the metal oxides. The flexibility of the MoS<sub>2</sub> nanosheet is also excellent that can act as the supportive structure for the metal nanoparticles. However, the MoS<sub>2</sub> nanosheets tend to get restacked on each other during the electrochemical cycle. This results in the increased thickness and reduced surface area. So, the scope of using MoS<sub>2</sub> nanosheet as a supercapacitor material is limited as mentioned in the comment. But it acts a good additive material when mixed with metal oxide nanoparticles to prepare supercapacitor electrode. The MoS<sub>2</sub> nanosheets would act as the conductive and support structure between the metal oxide nanoparticles at the same time the restacking of MoS<sub>2</sub> nanosheets would be prevented by the metal oxide nanoparticles present in between each nanosheets.

The use of SnO<sub>2</sub> for the electrochemical energy storage application can be considered due to the reasons such as higher theoretical specific capacity (781 mAh g<sup>-1</sup>), low synthesis cost, versatile nanostructure and morphology, low toxicity and non-carcinogenic. But the electrochemical instability caused by the volume expansion of SnO<sub>2</sub> nanoparticles limits the SnO<sub>2</sub> for the supercapacitor application. Use of SnO<sub>2</sub> nanoparticles functionalized MoS<sub>2</sub> nanosheets would mitigate the discontinuity issue caused by the volume expansion of SnO<sub>2</sub>. So, in MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite, the problems associated with each material are mitigated by other material to produce better electrochemical performance than the individual materials.

Figure 6.9 Cyclic voltammetry curves of bare SnO<sub>2</sub> nanoparticles and MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite at scanning speed of 30 mVs<sup>-1</sup> (material loading=1.1 mg cm<sup>-2</sup>)

The cyclic voltammetry (CV) was performed for SnO<sub>2</sub> and MoS<sub>2</sub>-SnO<sub>2</sub> between the potential value range of -0.2 V to 0.8 V. The CV plots are shown in Fig. 6.9. CV curves for all samples showed the double layer supercapacitor behavior with a semi-rectangular shape curve. This result is in accordance with the previously reported results (Bonu et al. 2016) (Krishnamoorthy et al. 2016). From Fig. 6.9, it is observed that the output current density of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite is higher than the output current density of the bare SnO<sub>2</sub> nanoparticles. During the electrochemical cycles, the SnO<sub>2</sub> nanoparticles undergo volume expansion that leads to increase in the particle size. The increase in particle size leads to microcracks between the SnO<sub>2</sub> particles (Lou et al. 2006) (Brousse et al. 1998). The formation of microcracks and the reduction in surface area were the reasons for the low performance of the SnO<sub>2</sub> nanoparticles. The addition of the MoS<sub>2</sub> nanosheets bridged the SnO<sub>2</sub> nanoparticles and offered a large surface area for the charge transportation between electrode and electrolyte. So, a gradual increase in the output current was observed with respect to increase in the MoS<sub>2</sub> to SnO<sub>2</sub> ratio. The 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite exhibited the highest current density amongst all the electrode materials. But the current density started to decrease when the

MoS<sub>2</sub> ratio was increased to 10%. So, it is concluded that the 5%, with highest electrochemical activity, is the optimum MoS<sub>2</sub>-SnO<sub>2</sub> ratio for the supercapacitor application.

Figure 6.10 Cyclic voltammety curves of 5% MoS<sub>2</sub>-SnO<sub>2</sub> at different scanning speeds, between an applied potential range of -0.2 V to 0.8 V (material loading=1.1 mg cm<sup>-2</sup>)

Figure 6.10 shows the CV curves of 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite at the scanning speeds of 10, 20, 30, 50 and 100 mVs<sup>-1</sup>, respectively. The obtained CV curves for all the scanning speeds are showing a semi-rectangular curve corresponding to double-layer capacitance.

The energy storage by the electric double layer capacitance is illustrated as Fig. 6.11.

Figure 6.11 Charging and discharging of an electric double layer supercapacitor

During charging, the electrode is negatively polarized by the applied voltage. The cations from the electrolyte are attracted to the negatively charged electrode to neutralize the charge. The formation of oppositely charged layers at the electrode surface is called the electric double layer. This way, the energy is physically stored or accumulated on the surface of the electrode. During discharging, the electrons flow to the external circuit from the electrode surface (Pal et al. 2019).

Figure 6.12 Galvanostatic charge-discharge curves of the SnO<sub>2</sub> and the MoS<sub>2</sub>-SnO<sub>2</sub> at the constant current density of 1 A g<sup>-1</sup>

Figure 6.13 Galvanostatic charge-discharge curves of 5% MoS<sub>2</sub>-SnO<sub>2</sub> at different current densities

Figure 6.12 shows the galvanostatic charge-discharge curves for the SnO<sub>2</sub> and the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite. The charge-discharge study was performed in the potential range of -0.2 V to 0.8 V at an applied current density of 1 A g<sup>-1</sup>. The obtained charge-discharge curves are linear and triangular in shape. This indicates the capacitance nature of the prepared electrode materials. The discharge time of the SnO<sub>2</sub> nanoparticles was 14 seconds, whereas the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite showed a longer discharge time. The discharge time was increased from 24 seconds for 0.5% MoS<sub>2</sub>-SnO<sub>2</sub> to 61 seconds for 5% MoS<sub>2</sub>-SnO<sub>2</sub>.

Figure 6.13 shows the galvanostatic charge-discharge curve of 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite at different current densities. The decrease in the charging and discharging time was observed when the current density was increased (Huang et al. 2014b). As the current is inversely proportional to the time ( $I=Q/t$ ), the increase in current density resulted in decreased discharge time ( $t_d$ ). The discharge time of 61, 21, 11, 5 seconds were measured for the applied current densities of 1, 2, 3 and 4 A g<sup>-1</sup>, respectively.

Figure 6.14 Schematic representation of the microcracks in the SnO<sub>2</sub> electrode and MoS<sub>2</sub> nanosheets bridging the microcracks

As mentioned earlier, the SnO<sub>2</sub> particles would go through volume or size change during the charge-discharge processes (Lou et al. 2006) (Brousse et al. 1998). This would lead to microcracks in the SnO<sub>2</sub> electrode. The discontinuities formed by these cracks would affect the charge transportation. But, when the MoS<sub>2</sub> nanosheets were introduced with the SnO<sub>2</sub> nanoparticles, the nanosheets acted as a conductive pathway between the SnO<sub>2</sub> nanoparticles. The MoS<sub>2</sub> nanosheets would anchor the SnO<sub>2</sub> nanoparticles within its surface and bridge the neighboring SnO<sub>2</sub> nanoparticles facilitating the easy charge transfer during the charge-discharge process (Huang et al. 2013). The large surface area of MoS<sub>2</sub> nanosheets leads to effective interaction between the electrode and the electrolyte. Thus, the electrochemical performance (CV curve area and discharge time) was increased for the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite. However, it was noticed that increasing the MoS<sub>2</sub> ratio beyond 5% led to a decrease in the discharge time. When the ratio of the MoS<sub>2</sub> was increased above the optimum value, the discharge time started to decrease because of the reduction in active SnO<sub>2</sub> material. So it is concluded that 5% is the optimum ratio of MoS<sub>2</sub> nanosheets in the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite. This is also in accordance with the cyclic voltammetry study.

Figure 6.15 Nyquist curve of SnO<sub>2</sub> and 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

Figure 6.16 Nyquist curve of SnO<sub>2</sub> and 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite: magnified at high frequency region

The Nyquist plot obtained from the electrochemical impedance spectroscopy (EIS) is shown in Fig. 6.15. EIS was performed over the frequency range of 0.1 Hz to 100 kHz for bare SnO<sub>2</sub> and 5% MoS<sub>2</sub>-SnO<sub>2</sub> and the plots are compared. A straight line was observed for both materials at the lower frequency region. However, the slope of the 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was higher than that of the bare SnO<sub>2</sub> nanoparticles. This proves that the diffusion resistance of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was lower than that of the bare SnO<sub>2</sub> nanoparticles. It indicated that the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite exhibited more ideal capacitor behavior than the bare SnO<sub>2</sub> nanoparticles. The high-frequency region was enlarged and shown in Fig. 6.16. The curves tend to show a very small semi-circle or loop in the high-frequency range indicates the minimum charge-transfer resistance in the material. It is attributed to the low charge transfer resistance of the electrode (Sreejesh et al. 2015). The solution resistance is the value at which the curve is intersecting with the real axis. The values were almost equal for 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite and SnO<sub>2</sub> nanoparticles with 3.67 and 3.6 Ω, respectively.

The specific capacitance was calculated from the charge-discharge curves by the following equation (Huang et al. 2013),

$$C_s = (I \cdot t_d) / (m \cdot \Delta V) \quad (1)$$

Where “ $C_s$ ” is the specific capacitance ( $F g^{-1}$ ), “ $I$ ” is the discharge current (A), “ $t_d$ ” is the discharge time (s), “ $m$ ” is the mass of the electrode material (g) and “ $\Delta V$ ” is the potential window. The values of  $C_s$  for  $SnO_2$  and  $MoS_2-SnO_2$  were plotted and shown in Fig. 6.17.

Figure 6.17 Specific capacitance of the  $MoS_2-SnO_2$  nanocomposites with different ratio of  $MoS_2$  in the composite

The specific capacitance ( $C_s$ ) of bare  $SnO_2$  nanoparticles was calculated as  $14 F g^{-1}$ . The specific capacitance value of the  $SnO_2$  is increased after the addition of the  $MoS_2$  nanosheets. The high surface area and easy charge transportation between the electrode material and electrolyte were the reason for the increased value of the specific capacitance. The 5%  $MoS_2-SnO_2$  nanocomposite showed the highest specific capacitance value of  $61.6 F g^{-1}$  which is 4.4 times greater than that of the bare  $SnO_2$  nanoparticles.

Figure 6.18 Capacitance retention versus the number of charge-discharge cycles for the 5% MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite

The capacitance retention curve of 5% MoS<sub>2</sub>-SnO<sub>2</sub> over the charge-discharge of 1000 cycles is shown in Fig. 6.18. The MoS<sub>2</sub>-SnO<sub>2</sub> showed excellent cyclic stability by retaining 90% of its original capacitance even after 1000 charge-discharge cycles. This indicates that the electrochemical performance of the SnO<sub>2</sub> nanoparticles is improved by the addition of the MoS<sub>2</sub> nanosheets with the SnO<sub>2</sub>. The reasons for the improvement in the performance are, (i) The MoS<sub>2</sub> nanosheets provided good support and conductive path in the electrode material when the microcracks are formed due to volume expansion of SnO<sub>2</sub>; (ii) The high surface area offered to the electrode in the form of nanosheets made it easier for the ion transportation between electrolyte and electrode.

### 6.3 Summary

The SnO<sub>2</sub> nanoparticles were synthesised by the solvothermal method. The synthesised SnO<sub>2</sub> nanoparticles have a spherical-like morphology with the size range of 10 nm to 32 nm. The nanocomposite of exfoliated MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles was prepared to improve the electrochemical performance of the SnO<sub>2</sub> towards the energy

storage application. The MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was prepared by functionalizing SnO<sub>2</sub> nanoparticles onto the surface of MoS<sub>2</sub> nanosheets by the ligand exchange process. The MoS<sub>2</sub> nanosheets mitigated the problem of volume expansion of SnO<sub>2</sub>. The MoS<sub>2</sub> nanosheets acted as the conducting bridge between the SnO<sub>2</sub> nanoparticles for charge transportation during the charge-discharge process. Also, the nanosheets provided helped to improve the interaction between the electrolyte and electrode material. The benefits achieved by the compositing SnO<sub>2</sub> nanoparticles with MoS<sub>2</sub> nanosheets enhanced the specific capacitance value from 14 F g<sup>-1</sup> to 61.6 F g<sup>-1</sup>. By improving the electrochemical performance of SnO<sub>2</sub>, the prepared MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite paves a way to develop low-cost energy storage devices in the future.

## CHAPTER 7

### ENHANCING THE ELECTROCHEMICAL PERFORMANCE OF THE ZnO ANODE FOR ALKALINE BATTERY APPLICATION

*This chapter discusses the synthesis and characterization of ZnO nanorods and ZnO microrods. The effect of size and shape of the ZnO on its electrochemical characteristics is studied in detail. The changes in electrochemical performance of ZnO in KOH electrolyte, owing to the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite additive, are examined by various analysis.*

#### 7.1 Synthesis of ZnO Nanorods and Microrods

Figure 7.1 FESEM micrograph of the microwave synthesised ZnO nanorods

Figure 7.2 FESEM micrograph of the synthesised ZnO microrods

Figure 7.3 FESEM micrograph of commercial ZnO nanoparticles

Figure 7.1 shows the FESEM micrograph of the ZnO nanorods (NRs) synthesised using microwave heating method. It is observed that the synthesised product shows one-directional growth of nanorods. The length of the nanorods is in the range of 300 nm to 500 nm. The diameter of the nanorods is measured to be less than 100 nm. Figure 7.2 shows the FESEM micrograph of the hydrothermally synthesised ZnO microrods (MRs). The micrograph shows that the synthesised microrods have a hexagonal cross-section. The average length of the ZnO microrods is 10  $\mu\text{m}$  and while the average diameter is 1  $\mu\text{m}$ . Figure 7.3 shows the FESEM micrograph of the commercial ZnO nanoparticles (NPs). It is observed that the commercial ZnO NPs contained particles with different morphologies, such as plate-like, sphere-like and cylinder-like with a size range of 70 nm to 300 nm

Figure 7.4 XRD patterns of commercial ZnO nanoparticles, microwave synthesised ZnO nanorods and hydrothermal synthesised ZnO microrods

Figure 7.4 shows the XRD patterns of the commercial ZnO nanoparticles, the microwave heated ZnO nanorods and the hydrothermally synthesised ZnO microrods. All the samples exhibit the peaks belonging to the ZnO wurtzite phase (ICDD 03-065-0523). The XRD patterns show that the ZnO nanoparticles and ZnO nanorods have preferred (101) orientation. But the relative intensity of the peak belonging to (101) plane is high for nanorods compared to that of the nanoparticles. On the other hand, the ZnO microrods show the preferred orientation of (002) plane. The preferred (002) orientation of ZnO microrods is attributed to its hexagonal cross-section.

Figure 7.5 Solubility of the ZnO samples in 6 M KOH solution

The stability of ZnO samples in high concentration alkaline electrolyte was studied by determining the quantity of zinc dissolved in 6 M KOH solution. In Zn alkaline battery, the high solubility of ZnO in the electrolyte leads to uneven deposition of the zinc during the charging process. That eventually leads to the growth of undesired dendrite structures on the ZnO anode (Mainar et al. 2018a). The atomic absorption spectroscopy (AAS) result (Fig. 7.5) revealed that the dissolved zinc from ZnO nanoparticles, nanorods and microrods is 480 µg/ml, 350 µg/ml and 85 µg/ml, respectively. The one-dimensional ZnO rods (Microrods and nanorods) are more stable in the KOH electrolyte than the commercial ZnO nanoparticles with plate-like and sphere-like morphology. It should be noted that the ZnO microrods showed excellent stability compared to other ZnO samples. It is attributed to the less surface area of the microrods due to their longer length and large diameter. Since the surface area is low, the material had less interaction with the KOH electrolyte, resulting in low solubility. However, the reason behind the low solubility of nanorods compared to the nanoparticles is due to its rod morphology having fewer edges and corners that are the hotspots for the dissolution (Ullah et al. 2013).

## 7.2 Electrochemical Reactions of the ZnO Anode in Alkaline Electrolyte

In alkaline batteries, the charging and discharging processes are ascribed to oxidation and reduction reactions of the ZnO with the alkaline electrolyte (Mainar et al. 2018a). During charging, the ZnO is converted into the zincate ions,  $\text{Zn(OH)}_4^{2-}$  (Eqn. 6). Then the zincate ions are reduced to metallic Zn (Eqn. 7). This is also called as Zn plating. During discharging, the Zn undergoes oxidation to form zincate ions (Eqn. 8). When the electrolyte solution close to the surface is saturated with the zincate ions, the zincate ions precipitate into ZnO. This is called as passivation process (Eqn. 9).

Charging/reduction reaction:

Discharging/oxidation reaction:

During charging, an undesired reaction occurs between the Zn and the water that lead to the evolution of hydrogen gas (Eqn. 10) (Mainar et al. 2018a) (Li and Dai 2014). The hydrogen evolution reaction (HER) from the Zn causes the corrosion of the Zn, water depletion in the electrolyte and increased internal pressure inside the battery (Mainar et al. 2018a).

This could be avoided by minimizing the solubility of zincate ions into the alkaline electrolyte and suppressing the hydrogen evolution reaction (HER). The recyclability and reversibility of the anode are improved by reducing the passivation of ZnO.

### 7.3 Effect of Size and Shape of the ZnO on its Electrochemical Properties

The effect of size and type of the morphology of ZnO on its electrochemical properties such as HER, corrosion behaviour, electrochemical kinetics, such as charge-transfer resistance and oxidation-reduction reactions are studied.

Figure 7.6 Cathodic polarization curves for commercial ZnO nanoparticles, microwave synthesised ZnO nanorods and hydrothermal synthesised ZnO microrods

The hydrogen evolution reaction (HER) or generation of hydrogen gas at the ZnO electrode is one of the major factors that deteriorate the performance of the zinc alkaline batteries (Dundálek et al. 2017) (Zhang et al. 2020c). The cathodic polarization study was performed to understand the influence of the size and shape of the active ZnO material on the hydrogen evolution. Figure 7.6 shows the cathodic polarization curves of ZnO nanoparticles, ZnO nanorods and ZnO microrods in the KOH electrolyte. The low current density from the ZnO microrods indicates its low HER activity. The HER activity of ZnO nanorods was higher than the ZnO nanoparticles in the beginning. However, the HER activity of the ZnO nanoparticles increased more than that from the nanorods towards the end that is observed by the higher current density from the ZnO nanoparticles.

Figure 7.7 Tafel polarization curves for the ZnO nanoparticles, ZnO nanorods and ZnO microrods

Figure 7.7 shows the Tafel polarization curves of the ZnO nanoparticles, ZnO nanorods and ZnO microrods. It is observed that the corrosion potential ( $E_{\text{corr}}$ ) for ZnO nanoparticles, ZnO nanorods and ZnO microrods is -1.565 V, -1.539 V and -1.516 V, respectively. The corrosion current ( $I_{\text{corr}}$ ) was determined as 3.15 mA/cm<sup>2</sup>, 2.42 mA/cm<sup>2</sup> and 1.815 mA/cm<sup>2</sup> for nanoparticles, nanorods and microrods, respectively. High ' $E_{\text{corr}}$ ' and low ' $I_{\text{corr}}$ ' attribute to the anti-corrosion behaviour of the material. The corrosion of Zn/ZnO is associated with the hydrogen evolution reaction (Li and Dai 2014)(Long et al. 2016). The ZnO microrods with high ' $E_{\text{corr}}$ ' and low ' $I_{\text{corr}}$ ' are less prone to corrosion. This is again due to its large diameter that offered less surface area to interact with the KOH electrolyte. The ZnO nanorods show the second-best performance against corrosion, while the ZnO nanoparticles with the sphere-like and plate-like morphologies were very prone to corrosion. It is inferred that the nanorod morphology of the ZnO was more stable than the spherical-like and plate-like morphology against corrosion.

Figure 7.8 a) Nyquist plots for the ZnO nanoparticles, ZnO nanorods and ZnO microrods, b) their corresponding Nyquist plots in high frequency region

Figure 7.8 shows the Nyquist plots obtained from the electrochemical impedance spectroscopy (EIS) for the ZnO nanoparticles, ZnO nanorods and ZnO microrods. The semi-circle in the high-frequency region denotes the charge-transfer resistance ( $R_{ct}$ ) between the ZnO electrode and the electrolyte. The Nyquist plots for all ZnO samples at the high-frequency region are shown in Fig. 7.8b. The diameter of the semi-circle denotes the charge-transfer resistance. The ' $R_{ct}$ ' values for the ZnO nanoparticles, ZnO nanorods and ZnO microrods are determined as 2.42  $\Omega$ , 2.2  $\Omega$  and 2.44  $\Omega$ , respectively. The charge-transfer resistance for the ZnO nanorods is relatively low compared to that of the ZnO nanoparticles and the ZnO microrods. The low ' $R_{ct}$ ' is attributed to reduced polarization in the material due to its uniform morphology and high electrochemical activity due to the high surface area (Chamoun et al. 2015) (Long et al. 2017b). The ' $R_{ct}$ ' value for the ZnO microrods was high due to the relatively low surface area that limited the electrochemical activity.

Figure 7.9, 7.10 and 7.11 show the cyclic voltammetry (CV) results of the ZnO nanoparticles, ZnO nanorods and ZnO microrods, respectively. The cyclic voltammetry curves explain the anodic and cathodic behaviour of the ZnO. The anodic and cathodic peaks of cyclic voltammetry are attributed to oxidation and reduction reactions of the corresponding material, respectively.

Figure 7.9 Cyclic voltammetry (CV) curves of commercial ZnO nanoparticles (material loading= 2 mg cm<sup>-2</sup>)

Figure 7.10 Cyclic voltammetry curves of microwave synthesised ZnO nanorods (material loading= 2 mg cm<sup>-2</sup>)

Figure 7.11 Cyclic voltammetry curves of hydrothermal synthesised ZnO microrods (material loading= 2 mg cm<sup>-2</sup>)

It is observed that the anodic and the cathodic peaks of the ZnO nanorods exhibit high current density compared to the ZnO nanoparticles and the ZnO microrods. This enhanced current density would result in an enlarged area under the CV curve. The increased area under the CV curve indicates the enhanced capacity of the material (Liu et al. 2019). The current densities at the anodic and cathodic peaks of the ZnO nanoparticles were the lowest. The reason behind the high electrochemical activity of the ZnO nanorod is due to their nanorods morphology and high specific surface area that enhanced the surface interaction between the ZnO and the electrolyte. The potential difference ( $\Delta E_{ac}$ ) between the anodic and the cathodic reactions is 0.274, 0.189 and 0.159 V for the ZnO nanoparticles, ZnO nanorods and ZnO microrods, respectively. The narrow ' $\Delta E_{ac}$ ' means a small potential difference between the charging and discharging process (Long et al. 2016).

It is observed that the current densities at anodic and cathodic peaks were decreased in the subsequent cycles for all ZnO samples. This decrease in the current density, indicated by the area under the CV curve attributes to the non-recyclability of the material (Peng et al. 2019). When the electrolyte solution near the electrode surface is saturated with the zincate ions, the zincate ions precipitate as a passive layer on the ZnO. The diffusion of OH<sup>-</sup> ions to the Zn is limited by this ZnO layer that would lead to the formation of thick ZnO (Mainar et al. 2018a). The reduction in current density of the second and the third cycle with respect to the first cycle was calculated. The  $I_2/I_1$  and  $I_3/I_1$  ratios of anodic and cathodic peaks for all ZnO materials are shown in Table 7.3. The anodic and cathodic current densities of the ZnO nanoparticles were reducing faster than that of the ZnO nanorods and the microrods. The small reduction in current densities for the ZnO microrods was due to its low solubility, which prevented the loss of zincate ions into the electrolyte. The decrease in current density could be minimized by avoiding the zincate dissolution into the electrolyte and improving the ionic transportation between the electrolyte and the ZnO electrode.

The further increase in the current density in the cathodic region after the cathodic peak is attributed to the hydrogen evolution reaction from the ZnO in the KOH solution (Gallaway et al. 2014) (Peng et al. 2019). It is observed that the current density from HER activity was notably higher compared to the current density corresponding to the

cathodic peak. Among all ZnO samples, the ZnO nanorods exhibited higher cathodic current density relative to that from HER activity. In contrast, the current density from HER activity was more prominent than that of cathodic reaction for the ZnO nanoparticles and the ZnO microrods.

Among bare ZnO samples (ZnO without any additives), the ZnO nanorods showed excellent output current density due to reduction and oxidation reactions. Also, it showed a good performance against corrosion due to its rod morphology.

#### 7.4 Effect of MoS<sub>2</sub>-SnO<sub>2</sub> additive on the electrochemical properties of the ZnO

TEM micrographs (Fig. 6.6) of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite were analysed in the chapter 6. It was established that the SnO<sub>2</sub> nanoparticles were functionalized on the surface of MoS<sub>2</sub> nanosheets. The MoS<sub>2</sub> nanosheets provide their surface to facilitate the charge transfer (Wang et al. 2016a). The SnO<sub>2</sub> has tendency to suppress the hydrogen gas evolution due to its high overpotential of hydrogen evolution reaction (HER) (Zheng et al. 2019).

Figure 7.12 Cathodic polarization curves for the ZnO nanoparticles, ZnO nanorods and ZnO microrods, with the MoS<sub>2</sub>-SnO<sub>2</sub> additive

The cathodic polarization curves for bare ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples are shown in Fig. 7.12. The MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO hybrid contained ZnO, MoS<sub>2</sub>-SnO<sub>2</sub> and PVA (binder) in the ratio of 75:15:10, respectively. It is observed that the current density for ZnO samples was reduced significantly after the addition of MoS<sub>2</sub>-SnO<sub>2</sub> with them. The decrease in the current density indicates the effect of MoS<sub>2</sub>-SnO<sub>2</sub> on suppressing the hydrogen evolution reaction. This is due to the high overpotential for hydrogen evolution of Sn and SnO<sub>2</sub> (Feng et al. 2014)(Zheng et al. 2019)(Yuan et al. 2005). Among all the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples, MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles showed high HER activity. MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods showed moderate HER activity, while MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods showed low HER activity.

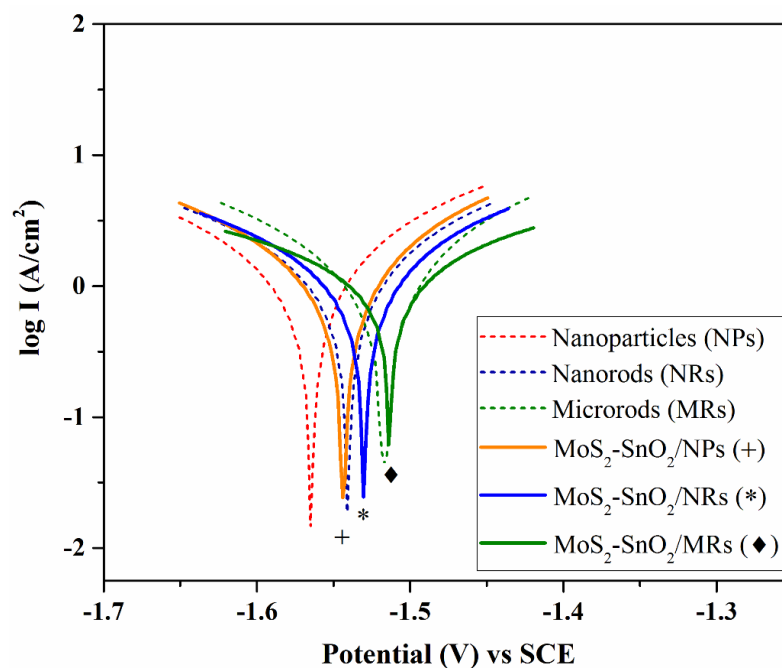

Figure 7.13 Tafel polarization curves for the ZnO nanoparticles, ZnO nanorods and ZnO microrods, with and without MoS<sub>2</sub>-SnO<sub>2</sub> additive

The Tafel polarization curves for all MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples are shown in Fig. 7.13. The Tafel plots for the bare ZnO samples are also shown for the comparison purpose. The effect of MoS<sub>2</sub>-SnO<sub>2</sub> additive on the inhibition of corrosion of ZnO is understood from the increase in 'E<sub>corr</sub>' values. The corrosion potential (E<sub>corr</sub>) and corrosion current density (I<sub>corr</sub>) values for the bare ZnO and the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples obtained from Tafel polarization are shown in Table 7.1.

Table 7.1 Tafel plot values for bare ZnO (commercial, microwave synthesised, hydrothermal synthesised) and the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples

Sample	ZnO NPs	ZnO NRs	ZnO MRs	MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO NPs	MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO NRs	MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO MRs
E <sub>corr</sub> (V)	-1.565	-1.539	-1.516	-1.544	-1.530	-1.514
I <sub>corr</sub> (mA/cm <sup>2</sup> )	3.15	2.42	1.815	2.86	1.87	1.678
Inhibition Efficiency (%)	-	23.2	42.4	9.2	40.6	46.7

The corrosion potential, 'E<sub>corr</sub>' values for the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples are shifted towards more positive values with respect to corresponding bare ZnO samples. The shift of 'E<sub>corr</sub>' to more positive indicates that the MoS<sub>2</sub>-SnO<sub>2</sub> additive made ZnO more anti-corrosion in the KOH electrolyte. Similarly, the corrosion current, 'I<sub>corr</sub>', which is attributed to the rate of corrosion was also reduced for the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples. The inhibition efficiency was calculated to determine the effect of MoS<sub>2</sub>-SnO<sub>2</sub> on inhibiting the corrosion. The inhibition efficiency for the ZnO samples with and without MoS<sub>2</sub>-SnO<sub>2</sub> additive was calculated by the formula given below (Long et al. 2017b).

$$\text{Inhibition efficiency} = (I_{\text{corr}}^0 - I_{\text{corr}}) / (I_{\text{corr}}^0) * 100 \quad (11)$$

Here, 'I<sub>corr</sub><sup>0</sup>' denotes the current density for the commercial ZnO nanoparticles. I<sub>corr</sub> represents other individual ZnO samples used in the present study. Table 7.1 recites that the inhibition efficiency for ZnO samples was improved after the addition of MoS<sub>2</sub>-SnO<sub>2</sub> to ZnO. The MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods and ZnO microrods showed high inhibition efficiency of 46.7% against corrosion. It is mainly because of their large diameter that offered low surface area to interact with the electrolyte. On the other hand, the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods showed the inhibition efficiency of 40.6%. The inhibition efficiency was improved significantly from 23.2% (bare ZnO nanorods) after

the addition of MoS<sub>2</sub>-SnO<sub>2</sub>. The MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles also showed a 9% inhibition efficiency against corrosion. As stated earlier, hydrogen evolution is the major factor for the corrosion of ZnO in the KOH electrolyte (Long et al. 2016). The addition of MoS<sub>2</sub>-SnO<sub>2</sub> to ZnO showed effectiveness in suppressing the HER activity by the cathodic polarization study mentioned already. So, the positive shift in ‘E<sub>corr</sub>’ and reduction in ‘I<sub>corr</sub>’ resulted from incorporating the MoS<sub>2</sub>-SnO<sub>2</sub> additive to the ZnO. The MoS<sub>2</sub>-SnO<sub>2</sub> passivated the ZnO surface that avoided the direct contact of ZnO with the electrolyte. This prevented the loss of zinc species into the electrolyte. These are the contributing factors for the improvement of the anti-corrosion behaviour of the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO composite samples.

Figure 7.14 Nyquist plots for the ZnO nanoparticles, ZnO nanorods and ZnO microrods, with MoS<sub>2</sub>-SnO<sub>2</sub> additive, b) their corresponding Nyquist plots in high-frequency region

Figure 7.14 shows the Nyquist plots of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles, MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods. The charge-transfer resistance (R<sub>ct</sub>) determined from the semi-circle in the high-frequency region is 1.705 Ω, 1.5 Ω and 1.82 Ω for the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles, MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods, respectively. Though the difference in ‘R<sub>ct</sub>’ of bare ZnO is narrow, the addition of MoS<sub>2</sub>-SnO<sub>2</sub> to ZnO reduced the charge-transfer resistance significantly in MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO. The decrease in charge-transfer resistance was the result of increased conductivity by the MoS<sub>2</sub>-SnO<sub>2</sub> incorporated with the ZnO. The MoS<sub>2</sub> nanosheets offered a large surface area to facilitate the charge transfer between

KOH electrolyte and ZnO particles/rods as well as the KOH electrolyte and the SnO<sub>2</sub> nanoparticles. Also, the SnO<sub>2</sub> nanoparticles that are in contact with the surface of ZnO enhanced its conductivity. The charge-transfer resistance is an important factor of an electrode material for the battery application. The potential loss is minimized due to the decreased charge-transfer resistance and it would result in better charge-discharge cycles (Chamoun et al. 2015). It is observed that the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods show the smallest 'R<sub>ct</sub>' value among bare ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples.

Figure 7.15 Cyclic voltammety curves of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles (material loading= 2 mg cm<sup>-2</sup>)

Figure 7.16 Cyclic voltammety curves of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods (material loading= 2 mg cm<sup>-2</sup>)

Figure 7.17 Cyclic voltammety curves of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods (material loading= 2 mg cm<sup>-2</sup>)

Figure 7.15 shows the CV result of the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles. The anodic and cathodic peak potentials are observed at -1.396 V and -1.602 V, respectively. The potential difference ( $\Delta E_{ac}$ ) between anodic and cathodic reactions is 0.206 V. The area under the CV curve of the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles is large compared to that of the bare ZnO nanoparticles. From the CV curve of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods (Fig. 7.16), the anodic and cathodic potentials are measured as -1.269 V and -1.84 V, respectively. The potential difference, ' $\Delta E_{ac}$ ' for MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods is 0.571 V. Similar to the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles, the area under the CV curve for ZnO nanorods is increased after the addition of MoS<sub>2</sub>-SnO<sub>2</sub> (Fig. 7.16). Figure 7.17 shows the CV result of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods. The potentials for the anodic and cathodic reaction are observed at -1.366 V and -1.609 V, respectively. The potential difference, ' $\Delta E_{ac}$ ' is 0.243 V. In contrast to other ZnO samples, the addition of MoS<sub>2</sub>-SnO<sub>2</sub> did not improve the anodic and cathodic current densities of ZnO microrods. The potential and current density values of the anodic and cathodic processes for the bare ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples are listed in Table 7.2.

Table 7.2 Potential and current density values of the anodic and cathodic processes for bare ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples

Samples	Anodic		Cathodic	
	Potential (V)	Current density (A/g)	Potential (V)	Current density (A/g)
ZnO NPs	-1.426	0.156	-1.700	-0.211
ZnO NRs	-1.517	4.712	-1.706	-1.595
ZnO MRs	-1.368	0.777	-1.527	-0.805
MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO NPs	-1.396	0.828	-1.602	-1.852
MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO NRs	-1.269	9.755	-1.84	-14.35
MoS <sub>2</sub> -SnO <sub>2</sub> /ZnO MRs	-1.366	0.163	-1.609	-0.527

The Nyquist plots (Fig. 7.14) showed that the addition of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite reduces the charge-transfer resistance between the ZnO and the electrolyte by forming a conductive network on the ZnO surface. The decrease in 'R<sub>ct</sub>' minimizes the potential losses (Chamoun et al. 2015). The enhanced output current densities and enlarged area under the CV curve for the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles and the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods resulted from improved conductivity due to the SnO<sub>2</sub> nanoparticles on the ZnO surface. Besides, the large surface area offered by the MoS<sub>2</sub> nanosheets acted as the active sites for ZnO and electrolyte interactions (Yang et al. 2018). It is observed that the anodic peak potential shifted to a more negative value for the second and third cycles with respect to the first cycle. Similarly, the cathodic peak potential shifted to a less negative value that minimizes the difference between the anodic and the cathodic potential. As the difference between the anodic and the cathodic potential becomes smaller, the reversibility of the material is improved (Zeng et al. 2017).

It is important to note that the effect of the hydrogen evolution reaction was suppressed after the addition of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite. It is seen by the decrease in current density with respect to the bare ZnO samples at the end of the cathodic sweep. The cathodic current densities for all MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples are higher than that derived

from HER activity. This is due to the high hydrogen evolution overpotential of the SnO<sub>2</sub> nanoparticles.

Table 7.3 Change in anodic and cathodic current densities for bare ZnO and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO samples

Reaction		ZnO NPs	ZnO NRs	ZnO MRs	MoS <sub>2</sub> - SnO <sub>2</sub> /ZnO NPs	MoS <sub>2</sub> - SnO <sub>2</sub> /ZnO NRs	MoS <sub>2</sub> - SnO <sub>2</sub> /ZnO MRs
Anodic	I <sub>2</sub> /I <sub>1</sub>	0.204	0.321	0.412	0.127	0.696	0.653
	I <sub>3</sub> /I <sub>1</sub>	0.131	0.159	0.205	0.052	0.493	0.485
Cathodic	I <sub>2</sub> /I <sub>1</sub>	0.364	0.624	0.814	0.113	0.778	0.702
	I <sub>3</sub> /I <sub>1</sub>	0.270	0.393	0.436	0.052	0.584	0.582

Table 7.3 shows the change in anodic and cathodic current densities for second and third cycles with respect to the first cycle. The I<sub>2</sub>/I<sub>1</sub> and I<sub>3</sub>/I<sub>1</sub> ratios are higher for the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods compared to the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles and the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods. This indicates that the recyclability is higher for MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods than MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles and MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods.

Figure 7.18 Interaction of the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods and the OH<sup>-</sup> ions from the electrolyte

Figure 7.18 shows the interaction of MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods and the OH<sup>-</sup> ions from the electrolyte. The addition of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite to ZnO samples reduced charge-transfer resistance due to improved conductivity. The large surface area and conductivity offered by the MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles helped to enhance the electrochemical activity of the ZnO. At the same time, the problem of corrosion and hydrogen evolution was minimized. Similar to the bare ZnO results, the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods showed better electrochemical performance than the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanoparticles and the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO microrods. Also, the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods showed significant improvement in suppressing HER activity, better anti-corrosion behaviour and enhanced output current density from the reduction and oxidation reactions.

## 7.5 Summary

The ZnO nanorods and the ZnO microrods were synthesised by microwave heating and hydrothermal method. The effect of size and morphology of the ZnO on its electrochemical performance in the KOH electrolyte was studied. The one-dimensional ZnO nanorods and microrods exhibited better stability and corrosion resistance than the ZnO nanoparticles with sphere-like and plate-like morphology. Among all bare ZnO

samples, the ZnO nanorods exhibited superior performance due to their high surface area and uniform rod morphology. The MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was prepared by functionalization of the SnO<sub>2</sub> nanoparticles on the surface of MoS<sub>2</sub> nanosheets. The influence of the MoS<sub>2</sub>-SnO<sub>2</sub> as an additive to the ZnO was evaluated. The MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite suppressed the hydrogen evolution reaction from the ZnO due to the high hydrogen overpotential of SnO<sub>2</sub>. The MoS<sub>2</sub>-SnO<sub>2</sub> passivated the ZnO surface that minimized the loss of zincate ions into the electrolyte, thus resulting in better anti-corrosion behaviour of the ZnO. The interaction between the ZnO and the electrolyte was improved by the larger area offered by the MoS<sub>2</sub> nanosheets. Also, the charge-transfer resistance of ZnO was decreased because of the conductive network formed by the MoS<sub>2</sub>-SnO<sub>2</sub>. These factors contributed in achieving higher output current density from the oxidation and reduction of the ZnO in the KOH electrolyte. The MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods exhibited excellent performance amongst all ZnO based samples due to their high surface area and nanorod morphology along with the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite additive.

U., “Enhancing the electrochemical performance of ZnO anode by novel additive of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite for the zinc alkaline battery application.” Accepted for publication in *Journal of Materials Science: Materials in Electronics*, Manuscript ID: JMSE-D-21-01860R1.

## CHAPTER 8

### CONCLUSIONS

The present study focussed on transparent conductive silver nanowires films and ZnO anode for future electronics and energy storage devices. This work aimed to enhance the growth of silver nanowires (Ag NWs) with new oxygen scavenger, Mn(II) ions and improving the electrochemical performance of ZnO in aqueous KOH electrolyte by tailoring its morphology and with a novel MoS<sub>2</sub>-SnO<sub>2</sub> additive.

The following conclusions are drawn from the results discussed in the previous chapters.

- Transparent conductive silver nanowires films were fabricated using the Ag NWs synthesised by the polyol method. The chloride conditions of CuCl<sub>2</sub> and MnCl<sub>2</sub> produced longer Ag NWs. This enhanced growth was due to the added Cu(II) ions or Mn(II) ions which acted as the oxygen scavenger to remove the atomic oxygen that blocked the active sites of the silver seed surfaces.
- The Ag NWs synthesised with the presence of Cu(II) ions (22 mM CuCl<sub>2</sub>) showed the mean length and diameter of 7.2 μm and 151 nm, respectively. On the other hand, the Ag NWs synthesised with the presence of Mn(II) ions (22 mM MnCl<sub>2</sub>) showed the mean length and diameter of 5.2 μm and 60 nm. The Ag NWs synthesised with MnCl<sub>2</sub> were thinner and more uniform in size (length and diameter) than those synthesised with CuCl<sub>2</sub>. This was attributed to the effective removal of atomic oxygen from silver seed surfaces by the Mn(II) ions.
- The concentration of MnCl<sub>2</sub> was optimized by synthesising Ag NWs with three different concentrations of MnCl<sub>2</sub> (22 mM, 40 mM and 65 mM). The 40 mM MnCl<sub>2</sub> produced Ag NWs with a high aspect ratio. Its mean length and diameter were measured as 7.7 μm and 80 nm. The fabricated transparent conductive Ag NWs (40 mM MnCl<sub>2</sub>) film exhibited the optical transmittance (%T<sub>550nm</sub>) of 79% and the sheet resistance of 29 Ω/sq.
- The mechanical flexibility of Ag NWs film was superior to commercial ITO film. After 500 bending cycles, the Ag NWs film showed a minimal increase in

the sheet resistance compared to the ITO film. The Ag NWs film was proved as an excellent transparent film heater by generating a temperature of 90 °C at the applied voltage of 10 V.

- The MoS<sub>2</sub> nanosheets were exfoliated by the ultrasonication-assisted method in the presence of PVP. The exfoliated MoS<sub>2</sub> nanosheets having a few-layer thickness were confirmed by electron microscopy (FESEM, TEM) and Raman spectroscopy. The exfoliated MoS<sub>2</sub> nanosheets showed a large surface area of 17 m<sup>2</sup> g<sup>-1</sup>.
- The SnO<sub>2</sub> nanoparticles were synthesised by the solvothermal method. The synthesised SnO<sub>2</sub> nanoparticles had spherical-like morphology with a size range of 10 nm to 32 nm. The nanocomposite of exfoliated MoS<sub>2</sub> nanosheets and SnO<sub>2</sub> nanoparticles was prepared by functionalizing the SnO<sub>2</sub> nanoparticles onto the surface of MoS<sub>2</sub> nanosheets by the ligand exchange process.
- The prepared MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was tested as the electrode material for supercapacitor application. The MoS<sub>2</sub> nanosheets significantly improved the electrochemical performance of the SnO<sub>2</sub> nanoparticles. The 5% MoS<sub>2</sub>-SnO<sub>2</sub> showed best performance among all MoS<sub>2</sub>-SnO<sub>2</sub> (0, 1, 2.5, 5 and 10% MoS<sub>2</sub>) samples. The specific capacitance of SnO<sub>2</sub> nanoparticles was increased from 14 F g<sup>-1</sup> to 61 F g<sup>-1</sup> by functionalizing them on the surface of MoS<sub>2</sub> nanosheets.
- The improved performance of the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite was attributed to the enhanced stability of SnO<sub>2</sub> nanoparticles by MoS<sub>2</sub> nanosheets. The MoS<sub>2</sub> nanosheets acted as the bridge between the SnO<sub>2</sub> nanoparticles. The large surface area of MoS<sub>2</sub> nanosheets enhanced the electrochemical interaction between the electrode and electrolyte.
- The ZnO nanorods and microrods were synthesised by microwave heating and hydrothermal method, respectively, for the zinc alkaline battery application. Their performance in the KOH electrolyte was evaluated and compared to that of commercial ZnO nanoparticles having plate-like and sphere-like morphology.
- The ZnO with one-dimensional rod morphology dissolved less in KOH solution than the commercial ZnO nanoparticles (NPs). The ZnO microrods (MRs) had the lowest solubility because of low surface interaction with KOH due to their

large diameter. The ZnO nanorods (NRs) were less soluble than the ZnO NPs owing to their smooth rod morphology with fewer edges and corners.

- The bare ZnO NRs showed better performance against hydrogen evolution and corrosion while the bare ZnO NPs were more prone to hydrogen evolution and corrosion. The ZnO NRs showed moderate hydrogen evolution and corrosion activities.
- The ZnO NRs showed highest electrochemical activity observed from cyclic voltammetry due to their low charge-transfer resistance, moderate resistance to solubility, hydrogen evolution, and corrosion in the KOH electrolyte.
- The addition of MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite improved the electrochemical performance of the ZnO. The hydrogen evolution reaction was decreased for all MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO hybrid samples because of the high hydrogen evolution overpotential of SnO<sub>2</sub>. The surface of ZnO was passivated by MoS<sub>2</sub>-SnO<sub>2</sub> that prevented the direct interaction with KOH electrolyte that minimized the corrosion of ZnO and the loss of zincate ions into the electrolyte.
- The charge transfer between ZnO and KOH electrolyte was improved by the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite addition that offered a large surface area and enhanced conductivity. Amongst all ZnO samples, the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods exhibited excellent electrochemical activity. It was observed by the increase in anodic and cathodic current densities in the cyclic voltammetry.
- The one-dimensional ZnO morphology with the MoS<sub>2</sub>-SnO<sub>2</sub> nanocomposite addition makes the MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO nanorods an excellent anode material for the zinc alkaline battery application.

### **Scope for the future work**

In the present study, the silver nanowires were synthesised by the polyol method in the presence of Mn(II) ions. The silver nanowires were synthesised with different concentrations of MnCl<sub>2</sub> without changing any other synthesis parameters. The addition of MnCl<sub>2</sub> during the synthesis process produced thin, uniform-length silver nanowires with a high aspect ratio. The study on the ZnO anode for the alkaline battery was carried out by tailoring the size and morphology of ZnO. The electrochemical performance of ZnO with MoS<sub>2</sub>-SnO<sub>2</sub> additive was evaluated. The ZnO nanorods with MoS<sub>2</sub>-SnO<sub>2</sub> additive exhibited excellent electrochemical performance in the KOH electrolyte. Based on the findings from the present study, the following studies are derived for future work.

- Multistep synthesis of silver nanowires using high molecular weight PVP with MnCl<sub>2</sub>, KBr in high pressure or nitrogen gas environment to produce long and thin silver nanowires.
- Fabrication of Zn-Ag coin cell battery using MoS<sub>2</sub>-SnO<sub>2</sub>/ZnO as the anode and silver nanowires as the cathode.
- Fabrication of Zn-Ag thin-film battery with sol-gel polymer/KOH electrolyte
- Performance evaluation of the fabricated Zn-Ag coin cell and Zn-Ag thin-film batteries.

## List of publications based on PhD Research Work

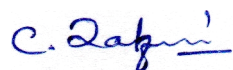

Sl. No.	Title of the paper/book chapter	Authors (in the same order as in the paper. Underline the Research Scholar's name)	Name of the Journal/book Conference/Symposium, Vol., No., Pages	Month & Year of Publication	Category *
1	Purification of silver nanowires synthesised by polyol method.	<u>Prabukumar C.</u> and Udaya Bhat K.	Materials Today: Proceedings Vol: 5, Page: 22487-22493	November 2018	3
2	Effect of solvent on the morphology of MoS <sub>2</sub> nanosheets prepared by ultrasonication-assisted exfoliation	<u>Prabukumar C.</u> , Sadiq M. M. J., Bhat D. K. and Udaya Bhat K.	AIP Conference Proceedings Vol.: 1943 Page: 020084	April 2018	3
3	SnO <sub>2</sub> nanoparticles functionalized MoS <sub>2</sub> nanosheets as the electrode material for supercapacitor applications	<u>Prabukumar C.</u> , Sadiq M. M. J., Bhat D. K. and Udaya Bhat K.	Materials Research Express Vol.: 6, Pages: 085526	May 2019	1
4	Beneficial Effect of Manganese (II) Ions on the Morphology of Polyol Synthesised Silver Nanowires	<u>Prabukumar C.</u> and Udaya Bhat K.	Electronic Materials Letters Vol.: 16, Pages: 264-275	April 2020	1
5	Enhancing the electrochemical performance of ZnO anode by novel additive of MoS <sub>2</sub> -SnO <sub>2</sub> nanocomposite for the zinc alkaline battery application	<u>Prabukumar C.</u> , Sunil Meti and Udaya Bhat K.	Journal of Materials Science: Materials in Electronics	<i>Accepted for Publication</i>	1

## BIO-DATA

Name : Prabukumar C.  
Father's name : Chinnusamy N.  
Date of Birth : 09-05-1989  
Permanent address : 4, C.H.B. colony west, Velur road,  
Tiruchengode, Namakkal - 637211  
Tamil Nadu.  
Contact number : +91-9740253476  
+91-9500933339  
E-mail ID : cprabumech@gmail.com

### Academic Qualification:

**Bachelor of Engineering (B.E.)** in Mechanical Engineering from Kongu Engineering College, Perundurai, Erode (Affiliated to Anna University, Chennai) (2010).

**Master of Technology (M.Tech.)** in Materials Engineering from National Institute of Technology, Karnataka (NITK), Surathkal (2014).
